PRINCIPLES OF NEURAL SCIENCE

Columns II (left) and IV (right) of the Edwin Smith Surgical Papyrus

This papyrus, transcribed in the Seventeenth Century B.C., is a medical treatise that contains the earliest reference to the brain anywhere in human records. According to James Breasted, who translated and published the document in 1930, the word brain coccurs only 8 times in ancient Egyptian, 6 of them on these pages. The papyrus describes here the symptoms, diagnosis, and prognosis of two patients with compound fractures of the skull, and compares the surface of the brain to "those ripples that happen in copper through smelting, with a thing in it that throbs and flutters under your fingers like the weak spot of the crown of a boy before it becomes whole for him." The red ink highlights the patients' ailments and their prognoses. (Reproduced, with permission, from the New York Academy of Medicine Library.)

DIM

Men ought to know that from the brain, and from the brain only, arise our pleasures, joys, laughter and jests, as well as our sorrows, pains, griefs and tears. Through it, in particular, we think, see, hear, and distinguish the ugly from the beautiful, the bad from the good, the pleasant from the unpleasant. . . . It is the same thing which makes us mad or delirious, inspires us with dread and fear, whether by night or by day, brings sleeplessness, inopportune mistakes, aimless anxieties, absent-mindedness, and acts that are contrary to habit. These things that we suffer all come from the brain, when it is not healthy, but becomes abnormally hot, cold, moist, or dry, or suffers any other unnatural affection to which it was not accustomed. Madness comes from its moistness. When the brain is abnormally moist, of necessity it moves, and when it moves neither sight nor hearing are still, but we see or hear now one thing and now another, and the tongue speaks in accordance with the things seen and heard on any occasion. But when the brain is still, a man can think properly.

Cover image: This image is a lithograph by F. Schima from a drawing by Sigmund Freud of the spinal ganglion of the lamprey Petromyzon. Before he discovered the unconscious, Freud had a promising career as a neural scientist. The cover thus recognizes that, a century after Freud's discovery, progress in the study of cognition has reemphasized the importance of unconscious mental processes for perception and action. (Reproduced, with permission, from Sigmund Freud, "Über Spinalganglien und Rückenmark der Petromyzon," Sitzungsberichte der Mathematisch-Naturwissenschaftlichen Classe der Kaiserlichen Akademie der Wissenschaften, LXXVIII. Band I. Abtheilung, 1878, copyright New York Academy of Medicine.)

James H. Schwartz 1933–2006

WE WISH TO DEDICATE THIS FIFTH EDITION of Principles of Neural Science to our friend and colleague, James H. Schwartz, one of the founding editors who died on March 13, 2006. Jimmy was an outstanding neuroscientist and scholar. His talent for science and his extraordinary erudition were evident from his days as a medical student at New York University. While at NYU he worked with Werner Maas in the microbiology department and carried an important set of studies on feedback inhibition in bacterial metabolism. This work was so impressive that upon completing

medical school, Jimmy was nominated for the highly selective graduate program in biology that had just been established at The Rockefeller University by Detlev Bronk. By the time Jimmy obtained his Ph.D. in Fritz Lippman's laboratory and graduated from Rockefeller in 1964, he had established himself as an outstanding biochemist. He was therefore eagerly recruited back to NYU in 1965 as an Assistant Professor in the Department of Microbiology.

There Jimmy turned to studying the nerve cells of the snail *Aplysia*, which were so large and uniquely identifiable that they seemed likely candidates for a study of neuronal biochemical identity. The immediate success of his initial studies encouraged him to devote himself completely to the nervous system. He rapidly became one of the leading biochemists on the nervous system and one of the leading thinkers regarding the relationship of brain to behavior.

The idea of going from molecules to behavior was the organizing theme of the first edition of *Principles of Neural Science*, which Jimmy co-edited. He simply loved working on *Principles*. A superb writer, he demanded precision in language both in himself and in others. This made him an exceptional editor. He read and avidly edited every chapter. In addition, Jimmy contributed his sense of historical scholarship. It was his idea to open *Principles* with the images of hieroglyphics from the Egyptian papyrus, the earliest reference to the brain in human record, which we include as the opening images in this edition as well. But perhaps most importantly, Jimmy championed the idea that this book should delineate fundamental principles rather than serve as an encyclopedia of facts. Thus, Jimmy's vision and editorial skill greatly enriched each of the five editions. In his absence we have striven to make the final product an edition that will continue to meet the high standards of readability and scholarship he set for all of us.

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Contents in Brief

Contents xiii
Preface xli
Acknowledgments xliii
Contributors xly

Part I

Overall Perspective

- 1 The Brain and Behavior 5
- 2 Nerve Cells, Neural Circuitry, and Behavior 21
- 3 Genes and Behavior 39

Part II

Cell and Molecular Biology of the Neuron

- 4 The Cells of the Nervous System 71
- 5 Ion Channels 100
- 6 Membrane Potential and the Passive Electrical Properties of the Neuron 126
- 7 Propagated Signaling: The Action Potential 148

Part III

Synaptic Transmission

- 8 Overview of Synaptic Transmission 177
- 9 Signaling at the Nerve-Muscle Synapse: Directly Gated Transmission 189
- 10 Synaptic Integration in the Central Nervous System 210

- 11 Modulation of Synaptic Transmission: Second Messengers 236
- 12 Transmitter Release 260
- 13 Neurotransmitters 289
- 14 Diseases of the Nerve and Motor Unit 307

Part IV

The Neural Basis of Cognition

- 15 The Organization of the Central Nervous System 337
- 16 The Functional Organization of Perception and Movement 356
- 17 From Nerve Cells to Cognition: The Internal Representations of Space and Action 370
- 18 The Organization of Cognition 392
- 19 Cognitive Functions of the Premotor Systems 412
- 20 Functional Imaging of Cognition 426

Part V

Perception

- 21 Sensory Coding 449
- 22 The Somatosensory System: Receptors and Central Pathways 475
- 23 Touch 498
- 24 Pain 530
- The Constructive Nature of Visual Processing 556

- 26 Low-Level Visual Processing: The Retina 577
- 27 Intermediate-Level Visual Processing and Visual Primitives 602
- 28 High-Level Visual Processing: Cognitive Influences 621
- 29 Visual Processing and Action 638
- 30 The Inner Ear 654
- 31 The Auditory Central Nervous System 682
- 32 Smell and Taste: The Chemical Senses 712

Part VI

Movement

- 33 The Organization and Planning of Movement 743
- 34 The Motor Unit and Muscle Action 768
- 35 Spinal Reflexes 790
- 36 Locomotion 812
- 37 Voluntary Movement: The Primary Motor Cortex 835
- 38 Voluntary Movement: The Parietal and Premotor Cortex 865
- 39 The Control of Gaze 894
- 40 The Vestibular System 917
- 41 Posture 935
- 42 The Cerebellum 960
- 43 The Basal Ganglia 982
- 44 Genetic Mechanisms in Degenerative Diseases of the Nervous System 999

Part VII

The Unconscious and Conscious Processing of Neural Information

- 45 The Sensory, Motor, and Reflex Functions of the Brain Stem 1019
- 46 The Modulatory Functions of the Brain Stem 1038

- 47 The Autonomic Motor System and the Hypothalamus 1056
- 48 Emotions and Feelings 1079
- 49 Homeostasis, Motivation, and Addictive States 1095
- 50 Seizures and Epilepsy 1116
- 51 Sleep and Dreaming 1140

Part VIII

Development and the Emergence of Behavior

- 52 Patterning the Nervous System 1165
- 53 Differentiation and Survival of Nerve Cells 1187
- 54 The Growth and Guidance of Axons 1209
- 55 Formation and Elimination of Synapses 1233
- 56 Experience and the Refinement of Synaptic Connections 1259
- 57 Repairing the Damaged Brain 1284
- 58 Sexual Differentiation of the Nervous System 1306
- 59 The Aging Brain 1328

Part IX

Language, Thought, Affect, and Learning

- 60 Language 1353
- 61 Disorders of Conscious and Unconscious Mental Processes 1373
- 62 Disorders of Thought and Volition: Schizophrenia 1389
- 63 Disorders of Mood and Anxiety 1402
- 64 Autism and Other Neurodevelopmental Disorders Affecting Cognition 1425
- 65 Learning and Memory 1441
- 66 Cellular Mechanisms of Implicit Memory Storage and the Biological Basis of Individuality 1461

67 Prefrontal Cortex, Hippocampus, and the Biology of Explicit Memory Storage 1487

Appendices

- A Review of Basic Circuit Theory 1525
- B The Neurological Examination of the Patient 1533

- C Circulation of the Brain 1550
- D The Blood–Brain Barrier, Choroid Plexus, and Cerebrospinal Fluid 1565
- E Neural Networks 1581
- F Theoretical Approaches to Neuroscience: Examples from Single Neurons to Networks 1601

Index 1619

Preface

The ultimate goal of neural science is to understand how the flow of electrical signals through neural circuits gives rise to mind—to how we perceive, act, think, learn, and remember. Although we are still many decades away from achieving this level of understanding, neuroscientists have made significant progress in gaining insight into the neural mechanisms underlying behavior, the observable output of the nervous systems of humans and other organisms. We are also beginning to understand the disorders of behavior associated with neurological and psychiatric disease. As in the earlier editions of this book, we emphasize in this edition that behavior can be examined in terms of the electrical activity of both individual neurons and systems of nerve cells by seeking answers to five basic questions. How does the brain develop? How do nerve cells in the brain communicate with one another? How do different patterns of interconnections give rise to different perceptions and motor acts? How is the communication between neurons modified by experience? How is that communication altered by disease?

When we published the first edition of this book in 1981, these questions could be addressed only in terms of cellular biology. By the fourth edition in 2000 the same problems were being studied at the molecular level. In the decade intervening between the fourth and the present edition, molecular biology has continued to enlighten the analysis of neurobiological problems. Molecular biology has made it possible to probe the pathogenesis of many neurological diseases, including several devastating genetic disorders: muscular dystrophy, retinoblastoma, neurofibromatosis, Huntington disease, and certain forms of Alzheimer disease. Molecular biology also has greatly expanded our understanding of how the brain develops. Genetically modified worms, flies, and mice have allowed us to relate single genes, including the mutant genes underlying neurological disease, to signaling in nerve cells and to an organism's behavior. At the same time new molecular and optical tools have made it possible to image the activity of individual neurons in the intact brain and to manipulate the electrical activity of neurons and neural circuits to alter behavior. Such experiments have made it possible to examine the molecular dynamics of nerve cells in the circuits responsible for cognitive processes.

Every disease that affects the nervous system has some inherited component. Now that the 20,000 genes of the human genome have been sequenced, it is possible to identify which genes make us susceptible to certain disorders and thus to predict an individual's predisposition to a particular illness. This knowledge of the human genome is beginning to transform the practice of medicine. An individual genome scan can quantify the personal risk for neurological and psychiatric disorders at levels of increasing detail and complexity. We therefore again stress vigorously our view—advocated since the first edition—that the future of clinical neurology and psychiatry depends on the progress of neural science.

Despite the power of molecular biology to elucidate molecular mechanisms of neural function and disease, any detailed understanding of how neurons act to generate complex behaviors requires an analysis of the circuitry in which the neurons participate. Thus, key questions in neuroscience include: How are neuronal assemblies formed during development? What are the computations performed by those neural circuits and how does this activity generate behavior? How are circuits modified during learning and memory? What are the changes in neural circuits that give rise to neurological and psychiatric disease? Although the cellular and molecular biological approaches emphasized in the previous editions will certainly continue to yield important information, knowledge of the function of assemblies of neurons in defined circuits must be attained to arrive at a comprehensive cognitive neuroscience.

To study how we perceive, act, think, learn, and remember, we must develop new approaches and conceptual schemes for understanding the behavior of systems that range from single nerve cells to the substrate of cognition. As a result, in this edition we discuss more fully how the cognitive and behavioral functions of the sensory and motor systems expand our treatment of cognitive processes, and incorporate into our discussion the increasing power and importance of computational neural science. Our ability to record the electrical activity and visualize functional changes in the brain during normal and abnormal mental activity permits even complex cognitive processes to be studied directly. No longer are we constrained simply to infer mental functions from observable behavior. Indeed, a new appreciation of Freud's original insight about the importance of unconscious processes—one of the major new themes to emerge in cognitive neural science—re-emphasizes the great limitation of restricting our analysis of mind to observable behaviors. As a result of its progress in describing unconscious mental processes, neural science may soon develop the tools needed to probe the deepest of biological mysteries the biological basis of consciousness and free will.

The intuitive insights that guided thinking about the mind at the time of our first edition in 1981 are proving inadequate in the 21st century. To give but one example, we intuitively sense that we perceive an object before interacting with it and we therefore fully expect that the brain acts in this sequential way. But recent studies indicate that at the highest levels the motor and sensory systems act in parallel, not in series, and that the motor system has considerable cognitive capability.

As a result of this progress, it has become easier to write a coherent introduction to the nervous system for students of behavior, biology, and medicine. Indeed, we think such a coherent summary is even more necessary now than it was with the first edition. Today neurobiology is central to the biological sciences—and indeed to science as a whole. Students of biology increasingly want to become familiar with neural

science, and most students of psychology consider themselves to be studying the biological basis of behavior. At the same time progress in neural science is providing clearer guidance to clinicians, particularly in the treatment of psychiatric disorders. In fact, perhaps the most significant change in the clinical landscape since the first edition is the realization that psychiatry can be a clinical neural science, that the progress of psychotherapy can be assessed quantitively using brain imaging. We therefore believe it is particularly important to clarify the major principles and mechanisms governing the functions of the nervous system in health and disease without becoming lost in details.

This book provides the detail necessary to meet the interests and requirements of students in particular fields but is organized in such a way that excursions into special topics are not necessary for grasping the major principles of neural science. Toward that end we have continued to refine the illustrations in the book to allow students to understand the fundamental concepts of neural science.

Throughout this book we document the central principle that all behavior is an expression of neural activity and illustrate the insights into behavior that neural science provides. With this fifth edition we again hope to encourage the next generation of undergraduate, graduate, and medical students to approach the study of behavior in a way that unites its biological and social dimensions. From ancient times, understanding human behavior has been central to civilized cultures. Engraved at the entrance to the Temple of Apollo at Delphi was the famous maxim "Know thyself." For us, the study of mind and consciousness defines the frontier of biology.

Eric R. Kandel Thomas M. Jessell Steven A. Siegelbaum A. J. Hudspeth

Acknowledgments

We were fortunate to have had the creative editorial assistance of Howard Beckman once again, who worked on the ongoing revisions of the fifth edition of *Principles of Neural Science* with the same characteristic demand for clarity of style and logic of argument that he has brought to previous editions. Without his assistance this edition would be a pale reflection of its previous editions.

Working on the other side of Manhattan at The Rockefeller University, away from the other editors at Columbia, Jim Hudspeth was responsible for the sections on Perception and Movement. In this lonely task Amy Miller, who cheerfully and accurately corrected the preliminary drafts of the relevant chapters, assisted him.

We owe a special debt to Sarah Mack who once again reinvented the entire art program. With her remarkable insight into science and detail, she produced remarkably clear, didactic, and artistically pleasing diagrams and images. We would like to thank our colleague Jane Dodd as well as Charles Lam, Becky Oles, and Terri Hamer for their help with the art program, and particularly Ann Canapary for her artistic contribution to the illustrations.

We appreciate the generous help that Neil McMillan, Jackie Stewart, and Mariah Widman provided with the figures.

A great debt is also owed to Clayton Eccard who managed the editorial project with intelligence and diligence, allowing us to bring the book to fruition.

We thank Millie Pellan, Kathy MacArthur, and especially Maria Palileo at Columbia University, who typed the many versions of the manuscript through the various editorial stages.

We are indebted to our colleagues at McGraw-Hill, Harriet Lebowitz, Eve Siegel, and Ann Sydor, for their invaluable help in the production of this edition and grateful for the assistance of Rajni Pisharody in the composition of the book.

Many other colleagues have helped the editors by critically reading many chapters of the book. We are especially indebted to John Krakauer and John Koester for their efforts, which proved to be invaluable. Most importantly we owe the greatest debt to the contributing authors of this edition.

We finally thank our spouses and families for their support and forbearance during the editorial process.

Preceding Page Over 30,000 years old, this paleolithic sculpture of a horse was discovered in the Vogelherd caves of southern Germany. Measuring only 5 cm and carved from mammoth ivory, this elegant sculpture is evidence of early human's capacity for remarkable perceptiveness and creativity. (Reproduced, with permission, from the University of Tübingen, copyright for Vogelherd, Horse. Photo: Hilde Jensen.)

Overall Perspective

URING THE SECOND HALF OF THE 20TH CENTURY, the central focus of biology was on the gene. Now in the first half of the 21st century, the central focus of biology has shifted to neural science and specifically to the biology of the mind. We need to understand the processes by which we perceive, act, learn, and remember. How does the brain—an organ weighing only three pounds—conceive of the infinite, discover new knowledge, and produce the remarkable individuality of human thoughts, feelings, and actions? How are these extraordinary mental capabilities distributed within the organ? How are different mental processes localized to specific combinations of regions in the brain? What rules relate the anatomical organization and the cellular physiology of a region to its specific role in mentation? To what extent are mental processes hardwired into the neural architecture of the brain? What do genes contribute to behavior, and how is gene expression in nerve cells regulated by developmental and learning processes? How does experience alter the way the brain processes subsequent events, and to what degree is that processing unconscious? Finally, what is the neural basis underlying neurological and psychiatric disease? In this introductory section of Principles of Neural Science, we attempt to address these questions. In so doing, we describe how neural science is attempting to link the logic of neural circuitry to the mind—how the activities of nerve cells within defined, neural circuits are related to the complexity of mental processes.

In the last several decades, technological advances have opened new horizons for the scientific study of the brain. Today, it is possible to link the molecular dynamics of interconnected circuits of cells to the internal representations of perceptual and motor acts in the brain and to relate these internal mechanisms to observable behavior. New imaging techniques permit us to visualize the human brain in action—to identify specific regions of the brain associated with particular modes of thinking and feeling and their patterns of interconnections.

In the first part of this book, we consider the degree to which mental functions can be located in specific regions of the brain. We also examine the extent to which the behavior so localized can be understood in terms of the properties of individual nerve cells and their interconnections in their specific region of the brain. In the later parts of the book, we examine in detail the cognitive and affective functions of the brain: perception, action, motivation, emotion, development, learning, and memory.

The human brain is a network of more than 100 billion individual nerve cells interconnected in systems—neural circuits—that construct our perceptions of the external world, fix our attention, and control the machinery of our actions. A first step toward understanding the mind, therefore, is to learn how neurons are organized into signaling pathways and how they communicate by means of synaptic transmission. One of the chief ideas we shall develop in this book is that the specificity of the synaptic connections established during development underlie perception, action, emotion, and learning. We must also understand both the innate (genetic) and environmental determinants of behavior. Specifically, we want to know how genes contribute to behavior. Behavior itself, of course, is not inherited—what is inherited is DNA. Genes encode proteins that are important for the development and regulation of the neural circuits that underlie behavior. The environment, which begins to exert its influence in utero, becomes of prime importance after birth, and environmental contingencies can in turn influence behavior by altering gene expression.

By means of the merger of molecular biology, neurophysiology, anatomy, developmental biology, and cell biology with the study of cognition, emotion, and behavior in animals and people, modern neural science has given rise to a new science of mind. Along with astute clinical observation, modern neural science has reinforced the idea first proposed by Hippocrates more than two millennia ago that the proper study of mind begins with study of the brain. Cognitive psychology and psychoanalytic theory in turn have emphasized the diversity and complexity of human mental experience. By emphasizing functional mental structure and internal representation, cognitive psychology has stressed the logic of mental operations and of internal representations. Experimental cognitive psychology and clinical psychotherapy can now be strengthened by insights into the neural science of behavior and by imaging mental processes in action in real time. The task for the years ahead is to produce a study of mental processes, grounded firmly in empirical neural science, yet still fully concerned with problems of how internal representations and states of mind are generated.

Chapter 2 Nerve Cells, Neural Circuitry, and Behavior

Chapter 3 Genes and Behavior

The Brain and Behavior

Two Opposing Views Have Been Advanced on the Relationship Between Brain and Behavior

The Brain Has Distinct Functional Regions

The First Strong Evidence for Localization of Cognitive Abilities Came from Studies of Language Disorders

Affective States Are Also Mediated by Local, Specialized Systems in the Brain

Mental Processes Are the End Product of the Interactions Between Elementary Processing Units in the Brain

HE LAST FRONTIER OF THE BIOLOGICAL SCIENCES the ultimate challenge—is to understand the biological basis of consciousness and the brain processes by which we feel, act, learn, and remember. During the past few decades, a remarkable unification within the biological sciences has set the stage for addressing this great challenge. The ability to sequence genes and infer the amino acid sequences of the proteins they encode has revealed unanticipated similarities between proteins in the nervous system and those encountered elsewhere in the body. As a result, it has become possible to establish a general plan for the function of cells, a plan that provides a common conceptual framework for all of cell biology, including cellular neural science. The current challenge in the unification within biology, which we outline in this book, is the unification of the study of behavior—the science of the mind—and neural science—the science of the brain.

Such a unified approach, in which mind and body are not viewed as separate entities, rests on the view that all behavior is the result of brain function. What we commonly call the mind is a set of operations carried out by the brain. Brain processes underlie not only simple motor behaviors such as walking and eating but also all the complex cognitive acts and behavior that we regard as quintessentially human—thinking, speaking, and creating works of art. As a corollary, all the behavioral disorders that characterize psychiatric illness—disorders of affect (feeling) and cognition (thought)—result from disturbances of brain function.

How do the billions of individual nerve cells in the brain produce behavior and cognitive states, and how are those cells influenced by the environment, which includes social experience? Explaining behavior in terms of the brain's activities is the task of neural science, and the progress of neural science in explaining human behavior is a major theme of this book.

Neural science must continually confront certain fundamental questions. Is a particular mental process carried out in specific regions of the brain, or does it involve the brain as a whole? If a mental process can be localized to discrete brain regions, what is the relationship between the functions of those regions in perception, movement, or thought and the anatomy and physiology of those regions? Are these relationships more likely to be understood by examining each region as a whole or by studying individual nerve cells?

To answer these questions we shall examine how modern neural science describes language, one of the most human of cognitive behaviors. In so doing we shall focus on the cerebral cortex, the part of the brain that is most highly developed in humans. We shall see how the cortex is organized into functionally distinct regions, each made up of large groups of neurons, and how the neural apparatus of a highly complex behavior can be analyzed in terms of the activity of specific sets of interconnected neurons within specific regions. In Chapter 2 we describe how neural circuits function at the cellular level, using a simple reflex behavior to show how the interplay of sensory signals and motor signals culminate in a motor act.

Two Opposing Views Have Been Advanced on the Relationship Between Brain and Behavior

Our views about nerve cells, the brain, and behavior emerged during the 20th century from a synthesis of five experimental traditions: anatomy, embryology, physiology, pharmacology, and psychology.

The 2nd century Greek physician Galen proposed that nerves convey fluid secreted by the brain and spinal cord to the body's periphery. His views dominated Western medicine until the microscope revealed the true structure of the cells in nervous tissue. Even so, nervous tissue did not become the subject of a special science until the late 1800s, when the Italian Camillo Golgi and the Spaniard Santiago Ramón y Cajal produced detailed, accurate descriptions of nerve cells.

Golgi developed a method of staining neurons with silver salts that revealed their entire cell structure under the microscope. He could see clearly that each neuron typically has a cell body and two types of processes: branching dendrites at one end and a long, cable-like axon at the other. Using Golgi's technique, Ramón y Cajal discovered that nervous tissue is not a syncytium, a continuous web of elements, but a network of discrete cells. In the course of this work Ramón y Cajal developed some of the key concepts and much of the early evidence for the *neuron doctrine*—the principle that individual neurons are the elementary building blocks and signaling elements of the nervous system.

In the 1920s support for the neuron doctrine was provided by the American embryologist Ross Harrison, who showed that dendrites and the axon grow from the cell body and that they do so even when each neuron is isolated from others in tissue culture. Harrison also confirmed Ramón y Cajal's suggestion that the tip of the axon gives rise to an expansion, the *growth cone*, which leads the developing axon to its target, either to other nerve cells or muscles. The final and definite proof of the neuron doctrine came in the mid-950s with the introduction of electron microscopy. A landmark study by Sanford Palay unambiguously demonstrated the existence of synapses, specialized regions that permit chemical or electrical signaling between neurons.

Physiological investigation of the nervous system began in the late 1700s when the Italian physician and physicist Luigi Galvani discovered that muscle and nerve cells produce electricity. Modern electrophysiology grew out of work in the 19th century by three German physiologists—Johannes Müller, Emil du Bois-Reymond, and Hermann von Helmholtz—who succeeded in measuring the speed of conduction of electrical activity along the axon of the nerve cell and further showed that the electrical activity of one nerve cell affects the activity of an adjacent cell in predictable ways.

Pharmacology made its first impact on our understanding of the nervous system and behavior at the end of the 19th century when Claude Bernard in France, Paul Ehrlich in Germany, and John Langley in England demonstrated that drugs do not act just anywhere on a cell, but rather bind discrete receptors typically located in the surface membrane of the cell. This insight led to the discovery that nerve cells can communicate with each other by chemical means.

Psychological thinking about behavior dates back to the beginnings of Western science when the ancient Greek philosophers speculated about the causes of behavior and the relation of the mind to the brain. In the 17th century René Descartes distinguished body and mind. In Descartes' dualistic view the brain mediates perception, motor acts, memory, appetites, and passions—everything that can be found in the lower animals. But the mind—the higher mental functions, the conscious experience characteristic of human behavior—is not represented in the brain or any other part of the body but in the soul, a spiritual entity that communicates with the machinery of the brain by means of the pineal gland, a tiny structure in the midline of the brain. Later in the 17th century Baruch Spinoza began to develop a unified view of mind and body.

In the 18th century Western ideas about the mind split along new lines. Empiricists believed that the brain is initially a blank slate (tabula rasa) that is later filled by sensory experience, whereas idealists, notably Immanuel Kant, believed that our perception of the world is determined by inherent features of our mind or brain. In the mid-19th century Charles Darwin set the stage for the modern understanding of the brain as the seat of all behavior. He also advanced the even more radical idea that animals could serve as models of human behavior. Thus the study of evolution gave rise to ethology, the investigation of the behavior of animals in their natural setting, and later to experimental psychology, the study of human and animal behavior under controlled conditions. At the beginning of the 20th century Sigmund Freud introduced

psychoanalysis. As the first systematic cognitive psychology, psychoanalysis framed the enormous problems that confront us in understanding the human mind.

Attempts to join biological and psychological concepts in the study of behavior began as early as 1800, when Franz Joseph Gall, a Viennese physician and neuroanatomist, proposed two radically new ideas. First, he advocated that the brain is the organ of the mind and that all mental functions emanate from the brain. In so doing, he rejected the idea that mind and body are separate entities. Second, he argued that the cerebral cortex did not function as a single organ but contained within it many organs, and that particular regions of the cerebral cortex control specific functions. Gall enumerated at least 27 distinct regions or organs of the cerebral cortex; later many more were added, each corresponding to a specific mental faculty. Gall assigned intellectual processes, such as the ability to evaluate causality, to calculate, and to sense order, to the front of the brain. Instinctive characteristics such as romantic love (amativeness) and combativeness were assigned to the back of the brain. Even the most abstract of human behaviors—generosity, secretiveness, and religiosity—were assigned a spot in the brain (Figure 1–1).

Although Gall's theory of localization was prescient, his experimental approach to localization was extremely naive. Rather than localize functions empirically, by looking into the brain and correlating defects in mental attributes with lesions in specific regions following tumor or stroke, Gall spurned all evidence derived from examination of brain lesions, discovered clinically or produced surgically in experimental animals. Influenced by physiognomy, the popular science based on the idea that facial features reveal character. Gall believed that the bumps and ridges on the skulls of people well endowed with specific faculties identified the centers for those faculties in the brain. He assumed that the size of an area of brain was related to the mental faculty represented in that area. Accordingly, exercise of a given mental faculty would cause the corresponding brain region to grow and this growth in turn would cause the overlying skull to protrude.

Gall first had this idea as a young boy when he noticed that those of his classmates who excelled at memorizing school assignments had prominent eyes. He concluded that this was the result of an overdevelopment of regions in the front of the brain involved in verbal memory. He developed this idea further when, as a young physician, he was placed in charge of an asylum for the insane in Vienna. There he began to study patients suffering from monomania, a disorder characterized by an exaggerated interest in some key idea

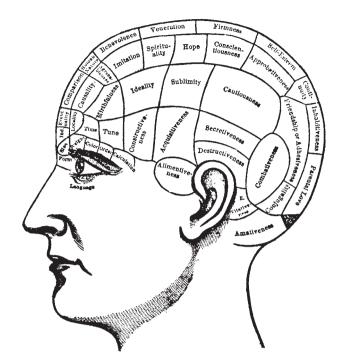

Figure 1–1 An early map of functional localization in the brain. According to the 19th century doctrine of phrenology, complex traits such as combativeness, spirituality, hope, and conscientiousness are controlled by specific areas in the brain, which expand as the traits develop. This enlargement of local areas of the brain was thought to produce characteristic bumps and ridges on the overlying skull, from which an individual's character could be determined. This map, taken from a drawing of the early 1800s, purports to show 42 intellectual and emotional faculties in distinct areas of the skull and the cerebral cortex underneath.

or a deep urge to engage in some specific behavior—theft, murder, eroticism, extreme religiosity. He reasoned that, because the patient functioned well in all other behaviors, the brain defect must be discrete and in principle could be localized by examining the skulls of these patients. Based on these findings Gall drew cortical maps such as those of Figure 1–1. Gall's studies of localized brain functions led to *phrenology*, a discipline concerned with determining personality and character based on the detailed shape of the skull.

In the late 1820s Gall's ideas were subjected to experimental analysis by the French physiologist Pierre Flourens. By systematically destroying Gall's functional centers in the brains of experimental animals, Flourens attempted to isolate the contribution of each "cerebral organ" to behavior. From these experiments Flourens concluded that specific brain regions are not

responsible for specific behaviors, but that all brain regions, especially the cerebral hemispheres of the forebrain, participate in every mental operation. Any part of a cerebral hemisphere, Flourens proposed, is able to perform all the hemisphere's functions. Injury to any one area of the cerebral hemisphere should therefore affect all higher functions equally. Thus in 1823 Flourens wrote: "All perceptions, all volitions occupy the same seat in these (cerebral) organs; the faculty of perceiving, of conceiving, of willing merely constitutes therefore a faculty which is essentially one."

The rapid acceptance of this belief, later called the *holistic* view of the brain, was based only partly on Flourens's experimental work. It also represented a cultural reaction against the materialistic view that the human mind is a biological organ. It represented a rejection of the notion that there is no soul, that all mental processes can be reduced to activity within the brain, and that the mind can be improved by exercising it, ideas that were unacceptable to the religious establishment and landed aristocracy of Europe.

The holistic view was seriously challenged, however, in the mid-19th century by the French neurologist Paul Pierre Broca, the German neurologist Carl Wernicke, and the British neurologist Hughlings Jackson. For example, in his studies of focal epilepsy, a disease characterized by convulsions that begin in a particular part of the body, Jackson showed that different motor and sensory functions could be traced to specific parts of the cerebral cortex. The regional studies of Broca, Wernicke, and Jackson were extended to the cellular level by Charles Sherrington and by

Box 1-1 The Central Nervous System

The Central Nervous System Has Seven Main Parts.

The **spinal cord**, the most caudal part of the central nervous system, receives and processes sensory information from the skin, joints, and muscles of the limbs and trunk and controls movement of the limbs and the trunk. It is subdivided into cervical, thoracic, lumbar, and sacral regions (Figure 1–2A).

The spinal cord continues rostrally as the **brain stem**, which consists of the medulla oblongata, pons, and midbrain. The brain stem receives sensory information from the skin and muscles of the head and provides the motor control for the head's musculature. It also conveys information from the spinal cord to the brain and from the brain to the spinal cord, and regulates levels of arousal and awareness through the reticular formation.

The brain stem contains several collections of cell bodies, the cranial nerve nuclei. Some of these nuclei receive information from the skin and muscles of the head; others control motor output to muscles of the face, neck, and eyes. Still others are specialized to process information from three of the special senses: hearing, balance, and taste.

The **medulla oblongata**, directly rostral to the spinal cord, includes several centers responsible for vital autonomic functions, such as digestion, breathing, and the control of heart rate.

The **pons**, rostral to the medulla, conveys information about movement from the cerebral hemispheres to the cerebellum.

The **cerebellum** lies behind the pons and is connected to the brain stem by several major fiber tracts called *peduncles*. The cerebellum modulates the force and range of movement and is involved in the learning of motor skills.

The **midbrain**, rostral to the pons, controls many sensory and motor functions, including eye movement and the coordination of visual and auditory reflexes.

The **diencephalon** lies rostral to the midbrain and contains two structures. The *thalamus* processes most of the information reaching the cerebral cortex from the rest of the central nervous system. The *hypothalamus* regulates autonomic, endocrine, and visceral functions.

The **cerebrum** comprises two cerebral hemispheres, each consisting of a heavily wrinkled outer layer (the *cerebral cortex*) and three deep-lying structures (the *basal ganglia*, the *hippocampus*, and the *amygdaloid nuclei*). The cerebral cortex is divided into four distinct lobes: frontal, parietal, occipital, and temporal (Figure 1–2B).

The basal ganglia participate in regulating motor performance; the hippocampus is involved with aspects of memory storage; and the amygdaloid nuclei coordinate the autonomic and endocrine responses of emotional states.

The brain is also commonly divided into three broader regions: the *hindbrain* (medulla oblongata, pons, and cerebellum), *midbrain*, and *forebrain* (diencephalon and cerebrum). The hindbrain (excluding the cerebellum) and midbrain together include the same structures as the brain stem.

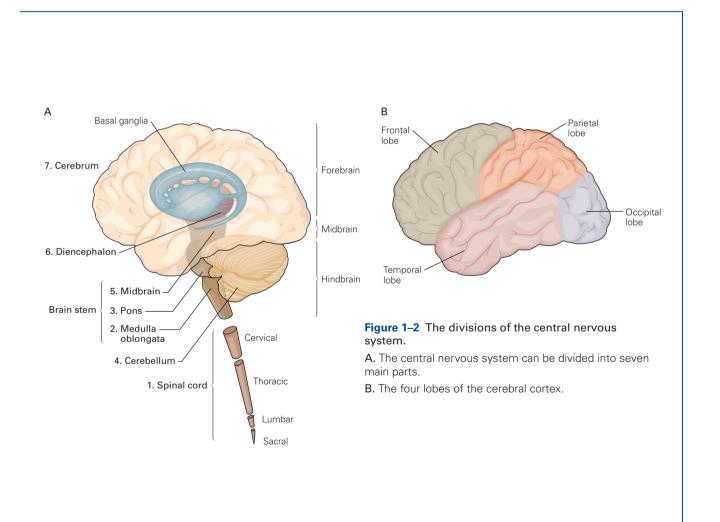

Ramón y Cajal, who championed the view of brain function called *cellular connectionism*. According to this view individual neurons are the signaling units of the brain; they are arranged in functional groups and connect to one another in a precise fashion. Wernicke's work and that of the French neurologist Jules Dejerine in particular revealed that different behaviors are produced by different interconnected brain regions.

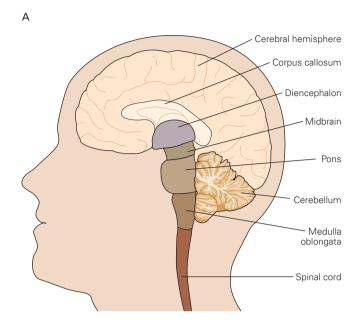

The first important evidence for localization emerged from studies of how the brain produces language. Before we consider the relevant clinical and anatomical studies, we shall first review the overall structure of the brain. (The anatomical organization of the nervous system is described in some detail in Chapter 17.)

The Brain Has Distinct Functional Regions

The central nervous system is a bilateral and essentially symmetrical structure with two main parts, the spinal cord and the brain. The brain comprises seven major structures: the medulla oblongata, pons, cerebellum, midbrain, diencephalon, and cerebrum (Box 1–1 and Figure 1–3).

Radiographic imaging techniques have made it possible to see these structures in living people. Brain imaging is now commonly used to evaluate the metabolic activity of discrete regions of the brain while people are engaged in specific tasks under controlled conditions. Such studies provide direct evidence that specific types of behavior involve particular regions of the brain. As a result, Gall's original idea that discrete

A. This schematic drawing shows the position of major structures of the brain in relation to external landmarks. Students

of brain anatomy quickly learn to discern the major internal landmarks, such as the corpus callosum, a large bundle of nerve fibers that connects the left and right hemispheres.

B. The major brain divisions drawn in **A** are also evident in a magnetic resonance image of a living human brain.

regions are specialized for different functions is now one of the cornerstones of modern brain science.

Students of the brain taking a cellular connectionist approach have found that the operations responsible for our cognitive abilities occur primarily in the cerebral cortex, the furrowed gray matter covering the two cerebral hemispheres. In each of the hemispheres the overlying cortex is divided into frontal, parietal, occipital, and temporal lobes (see Figure 1-2B), named for the skull bones that overlie them. Each lobe has several characteristic deep infoldings, an evolutionary strategy for packing more nerve cells into a limited space. The crests of these convolutions are called gyri, whereas the intervening grooves are called *sulci* or fissures. The more prominent gyri and sulci, which are quite similar from person to person, bear specific names. For example, the central sulcus separates the precentral gyrus, an area concerned with motor function, from the postcentral gyrus, an area that deals with sensory function (Figure 1–4A).

Each lobe has a specialized set of functions. The frontal lobe is largely concerned with short-term memory and planning future actions and with control of movement; the parietal lobe with somatic sensation, with forming a body image and relating it to extrapersonal

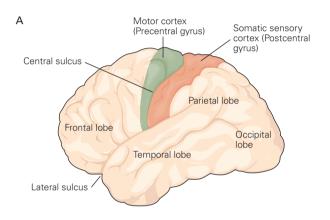

space; the occipital lobe with vision; and the temporal lobe with hearing and—through its deep structures, the hippocampus and amygdaloid nuclei—with learning, memory, and emotion.

Two important features characterize the organization of the cerebral cortex. First, each hemisphere is concerned primarily with sensory and motor processes on the contralateral (opposite) side of the body. Thus sensory information that reaches the spinal cord from the left side of the body crosses to the right side of the nervous system on its way to the cerebral cortex. Similarly, the motor areas in the right hemisphere exert control over the movements of the left half of the body. The second feature is that the hemispheres, although similar in appearance, are neither completely symmetrical in structure nor equivalent in function.

The First Strong Evidence for Localization of Cognitive Abilities Came from Studies of Language Disorders

The areas of the cortex that were first pinpointed to be important for cognition were concerned with language. These come from studies of *aphasia*, a language disorder that most often occurs when certain areas of brain tissue are destroyed by a stroke, the occlusion or rupture of a blood vessel to a portion of a cerebral hemisphere. Many of the important discoveries in the study of aphasia occurred in rapid succession during the last half of the 19th century. Taken together, these advances form one of the most exciting and important chapters in the neural science of human behavior.

Pierre Paul Broca, a French neurologist, was the first to identify specific areas of the brain concerned

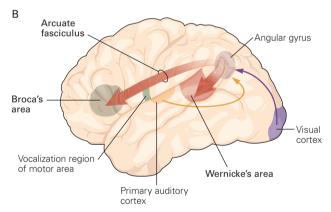

Figure 1–4 Major areas of the cerebral cortex are shown in this lateral view of the left hemisphere.

A. The four lobes of the cerebral cortex. The motor and somatic sensory areas of the cortex are separated by the central sulcus.

B. Areas involved in language. Wernicke's area processes auditory input for language and is important for understanding speech. It lies near the primary auditory cortex and the angular gyrus, which combines auditory input with information from other senses. Broca's area controls the production of intelligible speech. It lies near the region of the motor area that controls the mouth and tongue movements that form words. Wernicke's area communicates with Broca's area by a bidirectional pathway, part of which is made up of the arcuate fasciculus. (Adapted, with permission, from Geschwind 1979.)

with language. Broca was influenced by Gall's efforts to map higher functions in the brain, but instead of correlating behavior with bumps on the skull he correlated clinical evidence of aphasia with brain lesions discovered post mortem. In 1861 he wrote, "I had thought that if there were ever a phrenological science, it would be the phrenology of convolutions (*in the cortex*), and not the phrenology of bumps (*on the head*)." Based on this insight Broca founded *neuropsychology*, a science of mental processes that he distinguished from the phrenology of Gall.

In 1861 Broca described a patient, Leborgne, who as a result of a stroke could not speak, although he could understand language perfectly well. This patient had no motor deficits of the tongue, mouth, or vocal cords that would affect his ability to speak. In fact, he could utter isolated words, whistle, and sing a melody without difficulty. But he could not speak grammatically or create complete sentences, nor could he express ideas in writing. Postmortem examination of this patient's brain showed a lesion in the posterior region of the frontal lobe, now called *Broca's area* (Figure 1–4B). Broca studied eight similar patients, all with lesions in this region, and in each case the lesion was located in the left cerebral hemisphere. This discovery led Broca to announce in 1864: "Nous parlons avec l'hémisphère gauche!" (We speak with the left hemisphere!)

Broca's work stimulated a search for cortical sites associated with other specific behaviors—a search soon rewarded. In 1870 Gustav Fritsch and Eduard Hitzig galvanized the scientific community when they showed that characteristic limb movements of dogs, such as extending a paw, could be produced by electrically stimulating discrete regions of the precentral gyrus. These regions were invariably located in the contralateral motor cortex. Thus the right hand, the one most used for writing and skilled movements, is controlled by the left hemisphere, the same hemisphere that controls speech. In most people, therefore, the left hemisphere is regarded as *dominant*.

The next step was taken in 1876 by Karl Wernicke, who at age 26 published a now-classic paper, "The Symptom-Complex of Aphasia: A Psychological Study on an Anatomical Basis." In it he described another type of aphasia, a failure of comprehension rather than speech: a *receptive* as opposed to an *expressive* malfunction. Whereas Broca's patients could understand language but not speak, Wernicke's patient could form words but could not understand language. Moreover, the locus of this new type of aphasia was different from that described by Broca: The lesion occurred in the posterior part of the cortex where the temporal lobe meets the parietal and occipital lobes (Figure 1–4B).

On the basis of this discovery, and the work of Broca, Fritsch, and Hitzig, Wernicke formulated a neural model of language that attempted to reconcile and extend the two predominant theories of brain function at that time. Phrenologists and cellular connectionists argued that the cortex was a mosaic of functionally specific areas, whereas the holistic aggregate-field school claimed that every mental function involved the entire cerebral cortex. Wernicke proposed that only the most basic mental functions, those concerned with simple perceptual and motor activities, are mediated by neurons in discrete local areas of the cortex. More complex cognitive functions, he argued, result from interconnections between several functional sites. In placing the principle of localized function within a connectionist framework, Wernicke realized that different components of a single behavior are likely to be processed in several regions of the brain. He was thus the first to advance the idea of distributed processing, now a central tenet of neural science.

Wernicke postulated that language involves separate motor and sensory programs, each governed by distinct regions of cortex. He proposed that the motor program that governs the mouth movements for speech is located in Broca's area, suitably situated in front of that region of the motor area that controls the mouth, tongue, palate, and vocal cords (Figure 1–4B). He next assigned the sensory program that governs word perception to the temporal-lobe area that he had discovered, which is now called *Wernicke's area*. This region is conveniently surrounded by the auditory cortex and by areas now known collectively as *association cortex*, a region of cortex that integrates auditory, visual, and somatic sensations.

Thus Wernicke formulated the first coherent neural model for language that—with important modifications and elaborations we shall encounter in Chapter 60is still useful today. According to this model, the initial steps in neural processing of spoken or written words occur in separate sensory areas of the cortex specialized for auditory or visual information. This information is then conveyed to a cortical association area, the angular gyrus, specialized for processing both auditory and visual information. Here, according to Wernicke, spoken or written words are transformed into a neural sensory code shared by both speech and writing. This representation is conveyed to Wernicke's area, where it is recognized as language and associated with meaning. It is also relayed to Broca's area, which contains the rules, or grammar, for transforming the sensory representation into a motor representation that can be realized as spoken or written language. When this transformation from sensory to motor representation

cannot take place, the patient loses the ability to speak and write.

The power of Wernicke's model was not only its completeness but also its predictive utility. This model correctly predicted a third type of aphasia, one that results from disconnection. Here the receptive and expressive zones for speech are intact, but the neuronal fibers that connect them are destroyed. This conduction aphasia, as it is now called, is characterized by an incorrect use of words (paraphasia). Patients with conduction aphasia understand words that they hear and read and have no motor difficulties when they speak. Yet they cannot speak coherently; they omit parts of words or substitute incorrect sounds and in particular they have difficulties repeating phrases. Although painfully aware of their own errors, they are unable to put them right.

Inspired in part by Wernicke's advances and led by the anatomist Korbinian Brodmann, a new school of cortical localization arose in Germany at the beginning of the 20th century, one that distinguished functional areas of the cortex based on the shapes of cells and variations in their layered arrangement. Using this *cytoarchitectonic* method, Brodmann distinguished 52 anatomically and functionally distinct areas in the human cerebral cortex (Figure 1–5).

Even though the biological evidence for functionally discrete areas in the cortex was compelling, the aggregate-field view of the brain, not cellular connectionism, continued to dominate experimental thinking and clinical practice until 1950. This surprising state of affairs owed much to several prominent neural scientists who advocated for the aggregate-field view, among them the British neurologist Henry Head, the German neuropsychologist Kurt Goldstein, the Russian behavioral physiologist Ivan Pavlov, and the American psychologist Karl Lashley.

Most influential was Lashley, who was deeply skeptical of the cytoarchitectonic approach to functional mapping of the cortex. "The 'ideal' architectonic map is nearly worthless," Lashley wrote. "The area subdivisions are in large part anatomically meaningless, and misleading as to the presumptive functional divisions of the cortex." His skepticism was reinforced by his studies of the effects of various brain lesions on the ability of rats to learn to run a maze. From these studies Lashley concluded that the severity of a learning defect depended on the size of the lesion, not on its precise location. Disillusioned, Lashley—and after him many other psychologists—concluded that learning and other higher mental functions have no special locus in the brain and consequently cannot be attributed to specific collections of neurons.

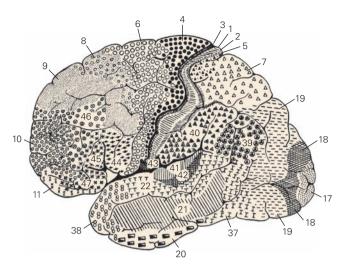

Figure 1–5 Brodmann's division of the human cerebral cortex into 52 discrete functional areas. Brodmann identified these areas on the basis of distinctive nerve cell structures and characteristic arrangements of cell layers. This scheme is still widely used today and is continually updated. Several areas defined by Brodmann have been found to control specific brain functions. For instance, area 4 is the motor cortex, responsible for voluntary movement. Areas 1, 2, and 3 constitute the primary somatosensory cortex, which receives sensory information primarily from the skin and joints. Area 17 is the primary visual cortex, which receives sensory signals from the eyes and relays them to other areas for further processing. Areas 41 and 42 constitute the primary auditory cortex. The drawing shows only areas visible on the outer surface of the cortex.

On the basis of his observations Lashley reformulated the aggregate-field view by further minimizing the role of individual neurons, specific neuronal connections, and even specific brain regions in the production of specific behavior. According to Lashley's theory of *mass action*, it is the full mass of the brain, not its regional components, that is crucial to function. Applying this idea to aphasia, Head and Goldstein asserted based on their clinical studies that language disorders can result from injury to almost any cortical area.

Lashley's experiments with rats and Head's clinical observations have now been reinterpreted. A variety of studies have shown that the maze-learning used by Lashley is unsuited to the search for local cortical functions because it involves so many motor and sensory capabilities. Deprived of one sensory capability, say vision, a rat can still learn to run a maze using touch or smell. Besides, as we shall see later in the book, many mental functions are mediated by more than one region or neuronal pathway. Thus a given function

may show anatomical redundancy and not be eliminated by a single lesion.

Soon the evidence for localization of function became overwhelming. Beginning in the late 1930s, Edgar Adrian in England and Wade Marshall and Philip Bard in the United States discovered that touching different parts of a cat's body elicits electrical activity in distinct regions of the cerebral cortex. By systematically probing the body surface they established a precise map of the body surface in specific areas of the cerebral cortex described by Brodmann. This result showed that functionally distinct areas of cortex can be defined unambiguously according to anatomical criteria such as cell type and cell layering, connections of cells, and—most importantly—behavioral function. As we shall see in later chapters, functional specialization is a key organizing principle in the cerebral cortex, extending even to individual columns of cells within a functional area. Indeed, the brain is divided into many more functional regions than Brodmann envisaged.

More refined methods have now made it possible to learn even more about the function of different brain regions involved in language. In the late 1950s Wilder Penfield, and later George Ojemann, reinvestigated the cortical areas that produce language. While locally anesthetized during brain surgery for epilepsy, awake patients were asked to name objects (or use language in other ways) while different areas of the exposed cortex were stimulated with small electrodes. If an area of the cortex was critical for language, application of the electrical stimulus blocked the patient's ability to name objects. In this way Penfield and Ojemann were able to confirm in the living, awake, and conscious brain—the language areas of the cortex described by Broca and Wernicke. In addition, Ojemann discovered other sites essential for language, in particular the insula, a region that lies deep to Broca's area. As we shall learn in Chapter 60 the neural networks for language are far more extensive and complex than those described by Broca and Wernicke.

Initially almost everything known about the anatomical organization of language came from studies of patients with brain lesions. Today positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) allow anatomical analysis to be conducted on healthy people engaged in reading, speaking, and thinking (Chapter 20). Functional MRI, a noninvasive imaging technique for visualizing activity in the brain, has not only confirmed that reading and speaking activate different brain areas but has also revealed that the act of *thinking* about a word's meaning in the absence of sensory inputs activates a still different area in the left frontal cortex (Figure 1–6).

A Looking at words

C Speaking words

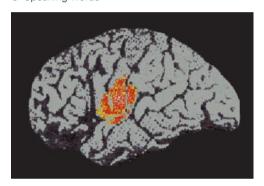

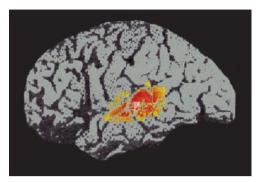

Figure 1–6 Specific regions of the cortex involved in the recognition of a spoken or written word can be identified with positron emission tomography (PET). Each of the four images of the human brain shown here (from the left side of the cerebrum) actually represents the averaged brain activity of several normal subjects. In these PET images white indicates areas of highest activity, red and yellow quite high activity, and blue and gray the areas of minimal activity. The "input" component of language (reading or hearing a word) activates the regions of the brain shown in A and B. The "output" component of language (speech or thought) activates the regions shown in C and D. (Reproduced, with permission, from Cathy Price.)

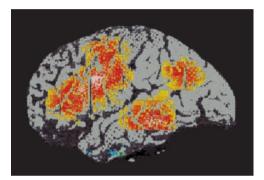

A. The reading of a single word produces a response both in the primary visual cortex and in the visual association cortex (see Figure 1–5).

B. Hearing a word activates the temporal cortex and the junction of the temporal-parietal cortex (see Figure 1–2). The same

B Listening to words

D Thinking of words

list of words used in the reading test (A) was used in the listening test. The results of the reading and listening tests show that the brain does not use the auditory pathway to convey a transformed visual signal.

C. Subjects were asked to repeat a word presented through earphones or on a screen. The spoken word activates the supplementary motor area of the medial frontal cortex. Broca's area is activated whether the word is heard or read. Thus both visual and auditory pathways converge on Broca's area, the common site for the motor articulation of speech.

D. Subjects were asked to respond to the word "brain" with an appropriate verb, for example, "to think." This type of task activates the frontal cortex as well as Broca's and Wernicke's areas. These areas play a role in all cognition and abstract representation.

In separate studies, Joy Hirsch and her colleagues, and Mariacristina Musso, Andrea Moro, and their colleagues used fMRI to explore more deeply Wernicke's idea that Broca's area contains the grammatical rules of language. Hirsch and her colleagues made the interesting discovery that processing of one's native language and processing of a second language occur in distinct regions within Broca's area. If the second language is acquired in adulthood, it is represented in a region

separate from that which represents the native language. If the second language is acquired early, however, both the native language and the second language are represented in a common region in Broca's area. These studies indicate that the age at which a language is acquired is a significant factor in determining the functional organization of Broca's area. In contrast, there is no evidence of such separate processing of different languages in Wernicke's area (Figure 1–7).

Further evidence for the fundamental role of Broca's area in processing grammatical rules emerges from the fMRI studies of Musso and Morro on the language instinct. Because language is a uniquely human capability, Charles Darwin suggested that the acquisition of language is an inborn instinct comparable to that for upright posture. Children acquire the grammar of their native language simply by listening to their parents speak. They do not have to be taught the specific rules of grammar. In 1960 the linguist Noam Chomsky elaborated on Darwin's notion. He proposed that children acquire a language so easily and naturally because humans, unlike other primates, have the innate capability of generalizing to a complete and coherent language from a limited sample of sentences. Based on an analysis of the structure of sentences in various languages, Chomsky argued that all natural languages share a common design, which he called universal grammar. The existence of universal grammar, he argued, implies that there is an innate system in the human brain that evolved to mediate this grammatical design of language.

This, of course, raised the question: Where in the brain does such a system reside? Is it in Broca's area, as Wernicke's model would suggest? Musso, Moro, and their colleagues asked this question and found that the region of Broca's area concerned with second language becomes established and increases in activity only when an individual learns a second language that is "natural," that is, one that shares the universal grammar. If the second language is an artificial language, a language that violates the rules of universal grammar, activity in Broca's area does not increase. Thus Broca's area must contain some kind of constraints that determine the structure of all natural languages.

Studies of patients with brain damage continue to afford important insight into how the brain is organized for language. One of the most impressive results comes from a study of deaf people who have lost their ability to communicate through American Sign Language (ASL) after suffering cerebral damage. ASL uses hand gestures rather than sound and is perceived by sight rather than sound but has the same structural

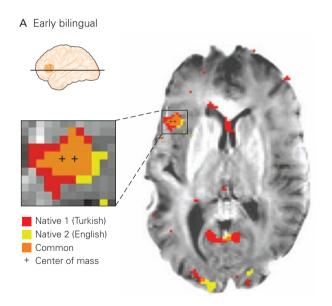

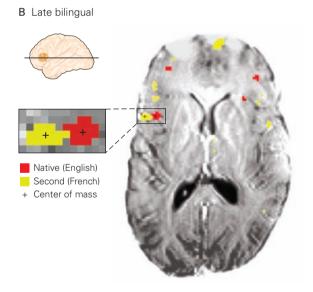

Figure 1–7 Functional magnetic resonance images of the brains of bilingual subjects during generation of narratives in two languages. These bilingual subjects were either "early" or "late" bilingual speakers; "early" bilinguals had learned two languages together prior to the age of 7 years, whereas "late" bilinguals acquired a second language after age 11 years. Axial slices of brain that intersect Broca's area are shown for one representative "early" bilingual subject and one representative "late" bilingual subject. Regions of the brain that responded during the narrative tasks are shown in red (native language) and yellow (native and second languages). In high-resolution views of these areas centroids of activity associated with each

language are indicated by (+) and areas of overlap between the two areas are shown in **orange**. (Reproduced, with permission, from Kim et al. 1997.)

A. In the early bilingual subject the locations of the centers and spread of activity for both languages are indistinguishable at the resolution of functional magnetic resonance imaging (fMRI) (1.5 \times 1.5 mm) as indicated by the close proximity of the two (+) and the orange region indicating sensitivity to both languages.

B. In the late bilingual subject both the locations of the centers (+) and the spread of the native and second language are distinguishable at the same resolution.

complexity as spoken languages. Signing is also localized to the left hemisphere; deaf people can become aphasic for sign language as a result of lesions in the left hemisphere, but not as a result of lesions in the right hemisphere. Damage to the left hemisphere can have quite specific consequences for signing just as for spoken language, affecting sign comprehension (following damage in Wernicke's area), grammar (following damage in Broca's area), or fluency.

These observations illustrate three points. First, the cognitive processing for language occurs in the left hemisphere and is independent of pathways that process the sensory and motor modalities used in language. Second, fully functional auditory and motor systems are not necessary conditions for the emergence and operation of language capabilities in the left hemisphere. Third, spoken language represents only one of a family of language skills mediated by the left hemisphere.

Similar conclusions that the brain has distinct cognitive systems have been reached from investigations of behaviors other than language. These studies demonstrate that complex information processing requires many distinct but interconnected cortical and sub-cortical areas, each concerned with processing some particular aspects of sensory stimuli or motor movement and not others. For example, in the visual system, a dorsal cortical pathway is concerned with *where* an object is located in the external world while a ventral pathway is concerned with *what* that object is.

Affective States Are Also Mediated by Local, Specialized Systems in the Brain

Despite the persuasive evidence for localized systems in the cortex dedicated to language, the idea nevertheless persisted that affective (emotional) functions could not be mediated by discrete specialized systems. Emotion, it was believed, must be an expression of whole-brain activity. Only recently has this view been modified. Although the neural systems governing emotion have not been mapped as precisely as the sensory, motor, and cognitive systems, distinct emotions can be elicited by stimulating specific parts of the brain in humans or experimental animals. The localization of neural systems regulating emotion has been dramatically demonstrated in patients with certain language disorders and in patients with a particular type of epilepsy that affects the regulation of affective states.

Some aphasic patients not only manifest cognitive defects in language but also have trouble with the affective aspects of language, such as intonation (prosody). These affective aspects are represented in the right hemisphere and, rather strikingly, the neural organization of

the affective elements of language mirrors the organization of the logical content of language in the left hemisphere. Damage to the right temporal area corresponding to Wernicke's area in the left temporal region leads to disturbances in comprehending emotional aspects of speech, for example the ability to appreciate from a person's tone of voice whether he is describing a sad or happy event. In contrast, damage to the right frontal area corresponding to Broca's area leads to difficulty in expressing emotional aspects of speech.

Thus some neurons needed for language also exist in the right hemisphere. Indeed, there is now considerable evidence that an intact right hemisphere is necessary to appreciate semantic subtleties of language, such as irony, metaphor, and wit, as well as the emotional content of speech. There is also preliminary evidence that the ability to enjoy and perform music involves systems in the right hemisphere.

Aprosodias, disorders of affective aspects of language that are localized to the right hemisphere, are classified as sensory, motor, or conductive, following the classification used for aphasias.

Although the localization of language appears to be inborn, it is by no means completely determined until the age of seven or eight. Young children in whom the left cerebral hemisphere is severely damaged early in life can still develop an essentially normal grasp of language, but they do so at a cost, for the ability of these children to locate objects in space or to reason spatially is much reduced compared to that of normal children.

Studies of patients with chronic temporal lobe epilepsy provide further clues to the areas in the brain that regulate affective states. These patients manifest characteristic emotional changes, some of which occur only fleetingly during the seizure itself (the so-called *ictal phenomena*). Common ictal phenomena include feelings of unreality; déjà vu, the sensation of having been in a place before or of having had a particular experience before; transient visual or auditory hallucinations; feelings of depersonalization, fear, or anger; delusions; inappropriate sexual feelings; and paranoia.

More enduring emotional changes, however, are evident when patients are not having seizures. These *interictal phenomena* are interesting because they resemble a coherent psychiatric syndrome. Such patients lose all interest in sex, and the decline in sexual interest is often paralleled by an increase in social aggressiveness. Most have one or more distinctive personality traits; they can be intensely emotional, ardently religious, extremely moralistic, or totally lacking in humor. In striking contrast, patients with epileptic foci outside the temporal lobe typically show no abnormal emotion and behavior.

Recent studies have found that high-frequency electrical stimulation of the subthalamic nucleus, part

of the motor system, can markedly improve the tremor characteristic of Parkinson disease, a movement disorder we consider in Chapter 41. Alim-Louis Benabid and his colleagues have found that stimulation of this region also induces unusual emotional states including euphoria, increased libido, feelings of merriment, infectious laughter, and hilarity—aspects of emotional expression that are depressed in Parkinson disease. One patient who previously was depressed and had suicidal thoughts began to enjoy himself again and abandoned his thoughts about suicide. He became creative once again, began a number of different projects, bought himself a new sports car, and began flirting with women.

Finally, one other important structure involved in the regulation of emotion is the amygdala, which lies deep within the cerebral hemispheres. Its role in emotion was discovered through studies of the effects of the lesions within the temporal lobe that produce epilepsy. The consequences of irritative lesions are exactly the opposite of those of destructive lesions resulting from a stroke or injury. Whereas destructive lesions bring about loss of function, often through the disconnection of related functional systems, the electrical activity brought about by epilepsy can increase activity in the regions in which the epileptic seizure occurs. In the case of amygdala seizures the increased activity leads to excessive expression of emotion. We consider the neurobiology of emotion in Part VII of this book.

Mental Processes Are the End Product of the Interactions Between Elementary Processing Units in the Brain

There are several reasons why the evidence for the localization of brain functions, which seems so obvious and compelling in retrospect, had been rejected so often in the past. Phrenologists introduced the idea of localization in an exaggerated form and without adequate evidence. They imagined each region of the cerebral cortex as an independent mental organ dedicated to a complete and distinct aspect of personality, much as the pancreas and the liver are independent digestive organs. Flourens's rejection of phrenology and the ensuing dialectic between proponents of the aggregate-field view (against localization) and the cellular connectionists (for localization) were responses to a theory that was simplistic and without adequate experimental evidence.

In the aftermath of Wernicke's discovery of the modular organization of language in the brain interconnected serial and parallel processing centers with more-or-less independent functions—we now think that all cognitive abilities result from the interaction of many processing mechanisms distributed in several regions of the brain. Specific brain regions are not responsible for specific mental faculties but instead are *elementary processing units*. Perception, movement, language, thought, and memory are all made possible by the interlinkage of serial and parallel processing in discrete brain regions, each with specific functions. As a result, damage to a single area need not result in the complete loss of a cognitive function (or faculty) as many earlier neurologists believed. Even if a behavior initially disappears, it may partially return as undamaged parts of the brain reorganize their linkages.

Thus it is not accurate to think of a mental process as being mediated by a chain of nerve cells connected in series—one cell connected directly to the next—for in such an arrangement the entire process breaks down when a single connection is disrupted. A more realistic metaphor is that of a process consisting of several parallel pathways in a communications network that can interact and ultimately converge upon a common set of target cells. The malfunction of a single pathway affects the information carried by it but need not disrupt the entire system. The remaining parts of the system can modify their performance to accommodate the breakdown of one pathway.

Modular processing in the brain was slow to be accepted because, until recently, it was difficult to demonstrate which components of a mental operation a particular pathway or brain region represented. Nor is it easy to define mental operations in a manner that leads to testable hypotheses. Only during the last several decades, with the convergence of modern cognitive psychology and the brain sciences, have we begun to appreciate that all mental functions can be broken down into subfunctions.

To illustrate this point, consider how we learn, store, and recall information about objects, people, and events. Simple introspection suggests that we store each piece of our knowledge as a single representation that can be recalled by memory-jogging stimuli or even by the imagination alone. Everything you know about your grandmother, for example, seems to be stored in one complete representation that is equally accessible whether you see her in person, hear her voice, or simply think about her. Our experience, however, is not a faithful guide to how knowledge is stored in memory. Knowledge about grandmother is not stored as a single representation but rather is subdivided into distinct categories and stored separately. One region of the brain stores information about the invariant physical features that trigger your visual recognition of her. Information about changeable aspects of her face—her expression and lip movements that relate to social communication—is stored in another region. The ability to recognize her voice is mediated in yet another region.

The most astonishing example of the modular organization of mental processes is the finding that our very sense of self—a self-aware coherent being, the sum of what we mean when we say "I"—is achieved through the connection of independent circuits in our two cerebral hemispheres, each mediating its own sense of awareness. The remarkable discovery that even consciousness is not a unitary process was made by Roger Sperry, Michael Gazzaniga, and Joseph Bogen in the course of studying patients in whom the corpus callosum—the major tract connecting the two cerebral hemispheres—was severed as a treatment for epilepsy. They found that each hemisphere had a consciousness that was able to function independently of the other.

Thus while one patient was reading a favorite book held in his left hand, the right hemisphere, which controls the left hand but cannot read, found that simply looking at the book was boring. The right hemisphere commanded the left hand to put the book down! Another patient would put on his clothes with the left hand while taking them off with the other. Each hemisphere has a mind of its own! In addition, the dominant hemisphere sometimes commented on the performance of the nondominant hemisphere, frequently manifesting a false sense of confidence regarding problems to which it could not know the solution, as the information was provided exclusively to the nondominant hemisphere.

Such studies have brought the study of consciousness to center stage in neural science. As we shall learn in Chapters 19, 20, and 61, consciousness, including self-consciousness, once the domain of philosophy, has been studied by neurobiologists such as Francis Crick, Christof Koch, Gerald Edelman, and Stanislas Dehaene. Neurobiologists do not concern themselves with the issue of subjectivity in conscious experience. Rather, they concentrate on understanding the neural correlates of consciousness—the pattern of neuronal activity associated with a specific conscious experience. Crick and Koch have focused on what they considered to be the simplest manifestation of consciousness: selective attention in visual perception. They believe a special and restricted population of neurons—perhaps only a few thousand cells—are responsible for this component. By contrast, Dehaene and Edelman believe that consciousness is a global property of the brain that involves vast numbers of nerve cells and a complex system of feed-forward broadcasting and feedback reentrant circuits.

As these examples illustrate, the main reason it has taken so long to appreciate which higher mental activities are mediated by particular regions of the brain is that we are dealing with biology's deepest riddle: the neural representation of consciousness and self-awareness. To be able to study the relationship between a mental process and specific brain regions, we must first identify the components of the mental process that we are attempting to explain. Of all behaviors, however, the higher mental processes are the most difficult to describe, to measure objectively, and to break down into elementary components. In addition, the brain's anatomy is immensely complex, and the structure and interconnections of its many parts are still not fully understood.

To analyze how a specific mental activity is processed in the brain, we must determine not only which aspects of the activity occur in which regions of the brain, but also how the mental activity is represented. Only in the last decade has this become possible. By combining the conceptual tools of cognitive psychology with new physiological techniques and brain-imaging methods, we are beginning to visualize the regions of the brain involved in particular behaviors. And we are beginning to discern how these behaviors can be described by a set of simpler mental operations and mapped to interconnected areas of the brain. Indeed, the excitement evident in neural science today stems from the conviction that at last we have the proper tools to explore empirically the organ of mental function and eventually to fathom the biological principles that underlie human behavior.

Nerve Cells, Neural Circuitry, and Behavior

The Nervous System Has Two Classes of Cells

Nerve Cells Are the Signaling Units of the Nervous System

Glial Cells Support Nerve Cells

Each Nerve Cell Is Part of a Circuit That Has One or More Specific Behavioral Functions

Signaling Is Organized in the Same Way in All Nerve Cells

The Input Component Produces Graded Local Signals

The Trigger Zone Makes the Decision to Generate an Action Potential

The Conductive Component Propagates an All-or-None Action Potential

The Output Component Releases Neurotransmitter

The Transformation of the Neural Signal from Sensory to Motor Is Illustrated by the Stretch-Reflex Pathway

Nerve Cells Differ Most at the Molecular Level

Neural Network Models Simulate the Brain's Parallel Processing of Information

Neural Connections Can Be Modified by Experience

THE REMARKABLE RANGE OF HUMAN behavior depends on a sophisticated array of sensory receptors connected to a highly flexible neural organ—the brain—that selects from among the stream of sensory signals those events in the environment that are important to the individual. In other words, the brain actively organizes perception, some of which is stored in memory for future reference, and some of which is transformed into immediate behavioral responses. All this is accomplished by interconnected nerve cells.

Individual nerve cells or neurons are the basic units of the brain. The human brain contains a huge number of these cells, on the order of 10¹¹ neurons, that can be classified into at least a thousand different types. Yet the complexity of human behavior depends less on the variety of neurons than on their organization into anatomical circuits with precise functions. One key organizational principle of the brain, therefore, is that nerve cells with similar properties can produce different actions because of the way they are interconnected.

Because relatively few principles of organization give rise to considerable complexity, it is possible to learn a great deal about how the nervous system produces behavior by focusing on five basic features of the nervous system:

- 1. The structural components of individual nerve cells;
- 2. The mechanisms by which neurons produce signals within and between nerve cells;
- 3. The patterns of connections between nerve cells and between nerve cells and their targets: muscles and gland effectors;
- 4. The relationship of different patterns of interconnection to different types of behavior; and
- 5. How neurons and their connections are modified by experience

The various parts of this book are organized around these five major topics. In this chapter we provide an overview of the neural control of behavior by introducing these topics together. We first consider the structure and function of neurons and the glial cells that surround and support them. We then examine how individual cells organize and transmit signals and how signaling between a few interconnected nerve cells produces a simple behavior, the knee-jerk reflex. Finally, we consider how changes in signaling by specific cells can modify behavior.

The Nervous System Has Two Classes of Cells

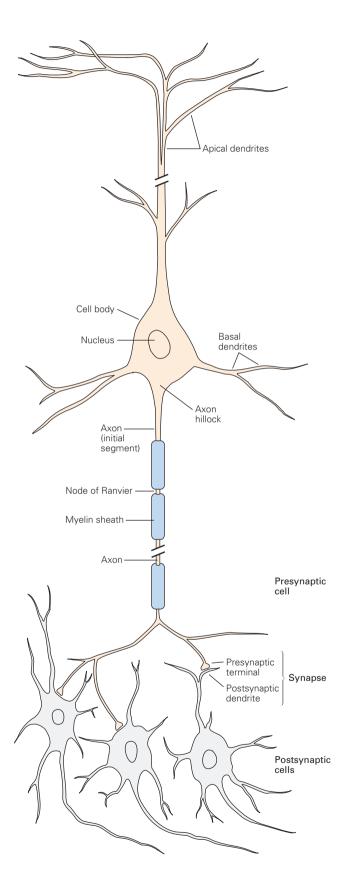

There are two main classes of cells in the nervous system: nerve cells, or neurons, and glial cells, or glia.

Nerve Cells Are the Signaling Units of the Nervous System

A typical neuron has four morphologically defined regions: (1) the cell body, (2) dendrites, (3) axon, and (4) presynaptic terminals (Figure 2–1). As we shall see later, each region has a distinct role in generating signals and communicating with other nerve cells.

The cell body or *soma* is the metabolic center of the cell. It contains the nucleus, which contains the genes of the cell, and the endoplasmic reticulum, an extension of the nucleus where the cell's proteins are synthesized. The cell body usually gives rise to two kinds of processes: several short *dendrites* and one long, tubular *axon*. Dendrites branch out in tree-like fashion and are the main apparatus for receiving incoming signals from other nerve cells. The axon typically extends some distance from the cell body and carries signals to other neurons. An axon can convey electrical signals over distances ranging from 0.1 mm to 2 m. These electrical signals, called *action potentials*, are initiated at a specialized trigger region near the origin of the axon

Figure 2-1 The structure of a neuron. Most neurons in the vertebrate nervous system have several main features in common. The cell body contains the nucleus, the storehouse of genetic information, and gives rise to two types of cell processes: axons and dendrites. Axons are the transmitting element of neurons; they vary greatly in length, some extending more than 2 m within the body. Most axons in the central nervous system are very thin (between 0.2 µm and 20 µm in diameter) compared with the diameter of the cell body (50 μm or more). Many axons are insulated by a sheath of fatty myelin that is regularly interrupted at gaps called the nodes of Ranvier. The action potential, the cell's conducting signal, is initiated at the initial segment of the axon and propagates to the synapse, the site at which signals flow from one neuron to another. Branches of the axon of the presynaptic neuron transmit signals to the postsynaptic cell. The branches of a single axon may form synapses with as many as 1,000 postsynaptic neurons. The apical and basal dendrites together with the cell body are the input elements of the neuron, receiving signals from other neurons.

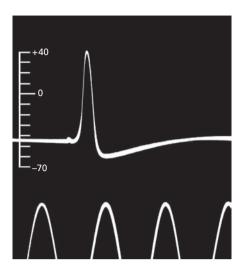

Figure 2–2 This historic tracing is the first published intracellular recording of an action potential. It was recorded in 1939 by Hodgkin and Huxley from a squid giant axon, using glass capillary electrodes filled with sea water. The timing pulses are separated by 2 ms. The vertical scale indicates the potential of the internal electrode in millivolts, the sea water outside being taken as zero potential. (Reproduced, with permission, from Hodgkin and Huxley 1939.)

called the *initial segment* from which they propagate down the axon without failure or distortion at speeds of 1 to 100 m/s. The amplitude of an action potential traveling down the axon remains constant at 100 mV because the action potential is an all-or-none impulse that is regenerated at regular intervals along the axon (Figure 2–2).

Action potentials are the signals by which the brain receives, analyzes, and conveys information. These signals are highly stereotyped throughout the nervous system, even though they are initiated by a great variety of events in the environment that impinge on our bodies—from light to mechanical contact, from odorants to pressure waves. The signals that convey information about vision are identical to those that carry information about odors. Here we see a key principle of brain function: the information conveyed by an action potential is determined not by the form of the signal but by the pathway the signal travels in the brain. The brain analyzes and interprets patterns of incoming electrical signals and their pathways, and in turn creates our sensations of sight, touch, smell, and sound.

To increase the speed by which action potentials are conducted, large axons are wrapped in an insulating sheath of a lipid substance, *myelin*. The sheath is interrupted at regular intervals by the nodes of

Ranvier, uninsulated spots on the axon where the action potential is regenerated. We shall learn more about myelination in Chapter 4 and about action potentials in Chapter 7.

Near its end the axon divides into fine branches that contact other neurons at specialized zones of communication known as *synapses*. The nerve cell transmitting a signal is called the *presynaptic cell*; the cell receiving the signal is the *postsynaptic cell*. The presynaptic cell transmits signals from specialized enlarged regions of its axon's branches, called *presynaptic terminals* or *nerve terminals*. The presynaptic and postsynaptic cells are separated by a very narrow space, the *synaptic cleft*. Most presynaptic terminals end on the postsynaptic neuron's dendrites; but the terminals may also terminate on the cell body or, less often, at the beginning or end of the axon of the receiving cell (see Figure 2–1).

As we saw in Chapter 1, Ramón y Cajal provided much of the early evidence for the neuron doctrine, the principle that each neuron is a discrete cell with distinctive processes arising from its cell body and that neurons are the signaling units of the nervous system. In retrospect it is hard to appreciate how difficult it was to persuade scientists of this elementary idea. Unlike other tissues, whose cells have simple shapes and fit into a single field of the light microscope, nerve cells have complex shapes. The elaborate patterns of dendrites and the seemingly endless course of some axons initially made it extremely difficult to establish a relationship between these elements. Even after the anatomists Jacob Schleiden and Theodor Schwann put forward the cell theory in the early 1830s—and the idea that cells are the structural units of all living matter became a central dogma of biology—most anatomists did not accept that the cell theory applied to the brain, which they thought of as a continuous, web-like reticulum of very thin processes.

The coherent structure of the neuron did not become clear until late in the 19th century, when Ramón y Cajal began to use the silver-staining method introduced by Golgi. Still used today, this method has two advantages. First, in a random manner that is not understood, the silver solution stains only about 1% of the cells in any particular brain region, making it possible to examine a single neuron in isolation from its neighbors. Second, the neurons that do take up the stain are delineated in their entirety, including the cell body, axon, and full dendritic tree. The stain reveals that there is no cytoplasmic continuity between neurons, even at synapses between two cells.

Ramón y Cajal applied Golgi's method to the embryonic nervous systems of many animals as well as humans. By examining the structure of neurons in almost every region of the nervous system, he could describe classes of nerve cells and map the precise connections between many of them. In this way Ramón y Cajal adduced, in addition to the neuron doctrine, two other principles of neural organization that would prove particularly valuable in studying communication in the nervous system.

The first of these has come to be known as the *principle of dynamic polarization*. It states that electrical signals within a nerve cell flow only in one direction: from the receiving sites of the neuron, usually the dendrites and cell body, to the trigger region at the axon. From there the action potential is propagated along the entire length of the axon to its terminals. In most neurons studied to date electrical signals in fact travel in one direction. Later in this chapter we describe the physiological basis of this principle.

The other principle advanced by Ramón y Cajal is that of *connectional specificity*, which states that nerve cells do not connect randomly with one another in the formation of networks. Rather each cell makes specific connections—at particular contact points—with certain postsynaptic target cells but not with others. The principles of dynamic polarization and connectional specificity are the basis of the modern connectionist approach to studying the brain.

Ramón y Cajal was also among the first to realize that the feature that most distinguishes one type of neuron from another is form, specifically the number of the processes arising from the cell body. Neurons are thus classified into three large groups: unipolar, bipolar, and multipolar.

Unipolar neurons are the simplest because they have a single primary process, which usually gives rise to many branches. One branch serves as the axon; other branches function as receiving structures (Figure 2–3A). These cells predominate in the nervous systems of invertebrates; in vertebrates they occur in the autonomic nervous system.

Bipolar neurons have an oval soma that gives rise to two distinct processes: a dendritic structure that receives signals from the periphery of the body and an axon that carries information toward the central nervous system (Figure 2–3B). Many sensory cells are bipolar, including those in the retina and in the olfactory epithelium of the nose. The receptor neurons that convey touch, pressure, and pain signals to the spinal cord, are variants of bipolar cells called *pseudo-unipolar* cells. These cells develop initially as bipolar cells but the two cell processes fuse into a single continuous structure that emerges from a single point in the cell body. The axon splits into two branches, one running to the

periphery (to sensory receptors in the skin, joints, and muscle) and another to the spinal cord (Figure 2–3C).

Multipolar neurons predominate in the nervous system of vertebrates. They typically have a single axon and many dendritic structures emerging from various points around the cell body (Figure 2–3D). Multipolar cells vary greatly in shape, especially in the length of their axons and in the extent, dimensions, and intricacy of their dendritic branching. Usually the extent of branching correlates with the number of synaptic contacts that other neurons make onto them. A spinal motor neuron with a relatively modest number of dendrites receives about 10,000 contacts—1,000 on the cell body and 9,000 on dendrites. The dendritic tree of a Purkinje cell in the cerebellum is much larger and bushier, receiving as many as a million contacts!

Nerve cells are also classified into three major functional categories: sensory neurons, motor neurons, and interneurons. Sensory neurons carry information from the body's peripheral sensors into the nervous system for the purpose of both perception and motor coordination. Some primary sensory neurons are called afferent neurons, and the two terms are used interchangeably. The term afferent (carried toward the central nervous system) applies to all information reaching the central nervous system from the periphery, whether or not this information leads to sensation. The term sensory should, strictly speaking, be applied only to afferent inputs that lead to perception. Motor neurons carry commands from the brain or spinal cord to muscles and glands (efferent information). Interneurons are the most numerous and are subdivided into two classes: relay and local. Relay or projection interneurons have long axons and convey signals over considerable distances, from one brain region to another. Local interneurons have short axons because they form connections with nearby neurons in local circuits.

Each functional classification can be subdivided further. Sensory system interneurons can be classified according to the type of sensory stimuli to which they respond; these initial classifications can be broken down still further, into many subgroups according to location, density, and size. For example, the retinal ganglion cell interneurons, which respond to light, are classified into 13 types based on the size of the dendritic tree, the branching density, and the depth of its location in specific layers of the retina (Figure 2–4).

Glial Cells Support Nerve Cells

Glial cells greatly outnumber neurons—there are 2 to 10 times more glia than neurons in the vertebrate central nervous system. The name for these cells derives

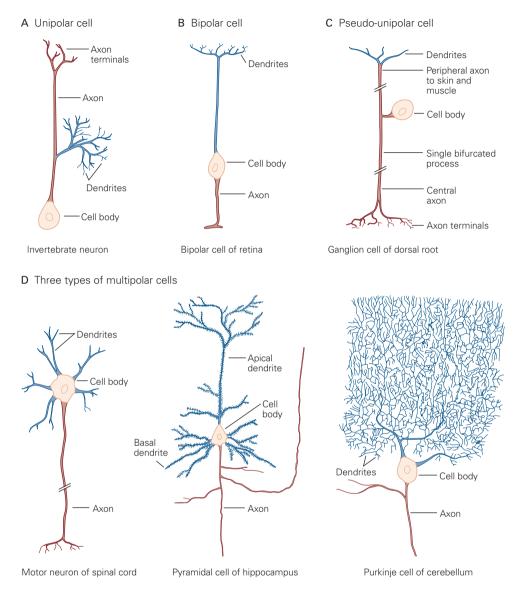

Figure 2–3 Neurons are classified as unipolar, bipolar, or multipolar according to the number of processes that originate from the cell body.

A. Unipolar cells have a single process emanating from the cell. Different segments serve as receptive surfaces or releasing terminals. Unipolar cells are characteristic of the invertebrate nervous system.

- **B.** Bipolar cells have two types of processes that are functionally specialized. The dendrite receives electrical signals and the axon transmits signals to other cells.
- C. Pseudo-unipolar cells are variants of bipolar cells that carry somatosensory information to the spinal cord. During development the two processes of the embryonic bipolar cell fuse and emerge from the cell body as a single process that has two functionally distinct segments. Both segments function as

axons; one extends to peripheral skin or muscle, the other to the central spinal cord. (Adapted, with permission, from Ramón y Cajal 1933.)

D. Multipolar cells have a single axon and many dendrites. They are the most common type of neuron in the mammalian nervous system. Three examples illustrate the large diversity of these cells. Spinal motor neurons innervate skeletal muscle fibers. Pyramidal cells have a roughly triangular cell body; dendrites emerge from both the apex (the apical dendrite) and the base (the basal dendrites). Pyramidal cells are found in the hippocampus and throughout the cerebral cortex. Purkinje cells of the cerebellum are characterized by a rich and extensive dendritic tree that accommodates an enormous synaptic input. (Adapted, with permission, from Ramón y Cajal 1933.)

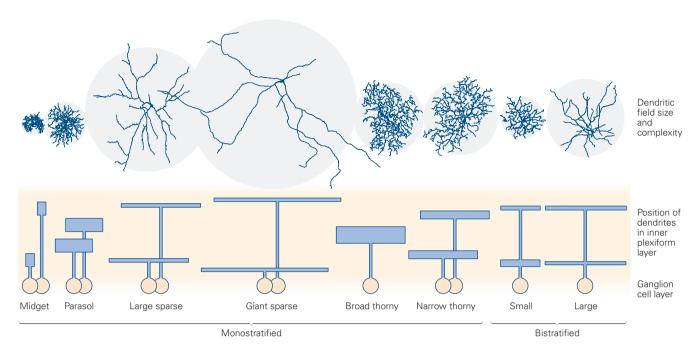

Figure 2–4 Sensory neurons can be subdivided into functionally distinct groups. Photodynamic staining distinguishes 13 types of retinal ganglion cells on the basis of their dendritic

shape and depth of position in the retina. (Reproduced, with permission, from Dacey et al. 2003.)

from the Greek for glue, but glia do not commonly hold nerve cells together. Rather, they surround the cell bodies, axons, and dendrites of neurons. Glia differ from neurons morphologically; they do not form dendrites and axons. Glia also differ functionally. Although they arise from the same embryonic precursor cells, they do not have the same membrane properties as neurons; are not electrically excitable; and are not directly involved in electrical signaling, which is the function of nerve cells.

There are many kinds of glial cells. As we will discuss in Chapter 4, the diversity in morphology of glial cells suggests that glia are probably as heterogeneous as neurons. Nonetheless, glia in the vertebrate nervous system can be divided into two major classes: microglia and macroglia. Microglia are immune system cells that are mobilized to present antigens and become phagocytes during injury, infection, or degenerative diseases. There are three main types of macroglia: oligodendrocytes, Schwann cells, and astrocytes. In the human brain about 80% of all the cells are macroglia. Of these, approximately half are oligodendrocytes and half are astrocytes.

Oligodendrocytes and Schwann cells are small cells with relatively few processes. Both cells form the myelin sheath that insulates an axon by tightly winding their membranous processes around the axon in a spiral.

Oligodendrocytes are found in the central nervous system; each cell envelops from one to 30 axonal segments (called internodes), depending on axon diameter (Figure 2–5A). Schwann cells occur in the peripheral nervous system, where each envelops a single segment of one axon (Figure 2–5B). Upon myelination, oligodendrocytes and Schwann cells influence axons by enhancing signal conduction and by segregating voltage-sensitive ion channels into distinct axonal domains (called node of Ranvier).

Astrocytes, the third main class of glial cells, owe their name to their irregular, roughly star-shaped cell bodies and large numbers of processes (Figure 2–5C). They comprise two major types. Protoplasmic astrocytes are found in the gray matter; their many processes end in sheet-like appendages. Fibrous astrocytes are found in the white matter and have long, fine processes that contain large bundles of tightly packed intermediate filaments. Both types of astrocytes have end-feet, dilatations that contact and surround capillaries and arterioles throughout the brain (Figure 2–5C). The sheet-like processes of protoplasmic astrocytes envelop nerve cell bodies and synapses, whereas the end-feet of fibrous astrocytes contact axons at the nodes of Ranvier.

The functions of astrocytes are still mysterious. It is generally thought that astrocytes are not essential

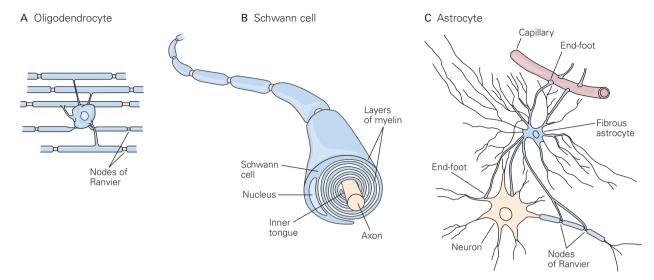

Figure 2–5 The principal types of glial cells are oligodendrocytes and astrocytes in the central nervous system and Schwann cells in the peripheral nervous system.

A. Oligodendrocytes are small cells with relatively few processes. In the white matter of the brain, as shown here, they provide the myelin sheaths that insulate axons. A single oligodendrocyte can wrap its membranous processes around many axons. In the gray matter perineural oligodendrocytes surround and support the cell bodies of neurons.

B. Schwann cells furnish the myelin sheaths for axons in the peripheral nervous system. During development several Schwann cells are positioned along the length of a single axon.

Each cell forms a myelin sheath approximately 1 mm long between two nodes of Ranvier. The sheath is formed as the inner tongue of the Schwann cell turns around the axon several times, wrapping the axon in layers of membrane. In actuality the layers of myelin are more compact than what is shown here. (Adapted, with permission, from Alberts et al. 2002.)

C. Astrocytes, a major class of glial cells in the central nervous system, are characterized by their star-like shape and the broad end-feet on their processes. Because these end-feet put the astrocyte into contact with both capillaries and neurons, astrocytes are thought to have a nutritive function. Astrocytes also play an important role in maintaining the blood-brain barrier (See Appendix D).

for information processing but support neurons in four ways:

- Astrocytes separate cells, thereby insulating neuronal groups and synaptic connections from each other.
- 2. Because astrocytes are highly permeable to K⁺, they help regulate the K⁺ concentration in the space between neurons. As we shall learn below, K⁺ flows out of neurons when they fire. Repetitive firing may create excess extracellular K⁺ that could interfere with signaling between cells in the vicinity. Astrocytes can take up the excess K⁺ and thus maintain the efficiency of signaling between neurons.
- 3. Astrocytes perform other important housekeeping chores that promote efficient signaling between neurons. For example, as we shall learn later, they take up neurotransmitters from synaptic zones after release.
- 4. Astrocytes help nourish surrounding neurons by releasing growth factors.

Although glial cells do not generate action potentials, they have recently been found to participate in neuron-glial signaling processes. The significance of this signaling is still poorly understood, but it may actively help regulate synapse development and function (Chapter 4).

Each Nerve Cell Is Part of a Circuit That Has One or More Specific Behavioral Functions

Every behavior is mediated by specific sets of interconnected neurons, and every neuron's behavioral function is determined by its connections with other neurons. We can illustrate this with a simple behavior, the knee-jerk reflex. The reflex is initiated when a transient imbalance of the body stretches the quadriceps extensor muscles of the leg. This stretching elicits sensory information that is conveyed to motor neurons, which in turn sends commands to the extensor muscles to contract so that balance is restored. This reflex is useful for clinically, but the underlying mechanism is important because it continuously maintains normal tone in the quadriceps and prevents our knees from buckling when we stand or walk.

The tendon of the quadriceps femoris, an extensor muscle that moves the lower leg, is attached to the tibia through the tendon of the kneecap. Tapping this tendon just below the patella stretches the quadriceps femoris. This stretch initiates reflex contraction of the quadriceps muscle to produce the familiar knee jerk. By increasing the tension of a select group of muscles, the stretch reflex changes the position of the leg, suddenly extending it outward (Figure 2–6).

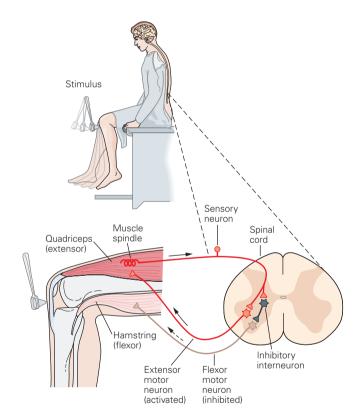

Figure 2–6 The knee-jerk reflex is controlled by a simple circuit of sensory and motor neurons. Tapping the kneecap with a reflex hammer pulls on the tendon of the quadriceps femoris, a muscle that extends the lower leg. When the muscle stretches in response to the pull of the tendon, information regarding this change in the muscle is conveyed to the central nervous system by sensory neurons. In the spinal cord the sensory neurons form excitatory synapses with extensor motor neurons that contract the quadriceps, the muscle that was stretched. The sensory neurons act indirectly, through interneurons, to inhibit flexor motor neurons that would otherwise contract the opposing muscle, the hamstring. These actions combine to produce the reflex behavior. In the drawing each extensor and flexor motor neuron represents a population of many cells.

The cell bodies of the sensory neurons involved in the knee-jerk reflex are clustered near the spinal cord in the dorsal root ganglia. They are pseudo-unipolar cells; one branch of each cell's axon runs to the quadriceps muscle at the periphery, whereas the other runs centrally into the spinal cord. The branch that innervates the quadriceps makes contact with stretchsensitive receptors (muscle spindles) and is excited when the muscle is stretched. The branch reaching the spinal cord forms excitatory connections with the motor neurons that innervate the quadriceps and control its contraction. This branch also contacts local interneurons that *inhibit* the motor neurons controlling the opposing flexor muscles (Figure 2–6). These local interneurons are not involved in producing the stretch reflex itself, but by coordinating motor action they increase the stability of the reflex. Thus the electrical signals that produce the stretch reflex carry four kinds of information:

- 1. Sensory information is conveyed to the central nervous system (the spinal cord) from muscle.
- 2. Motor commands from the central nervous system are issued to the muscles that carry out the knee jerk.
- 3. Inhibitory commands are issued to motor neurons that innervate opposing muscles, providing coordination of muscle action.
- 4. Information about local neuronal activity related to the knee jerk is sent to higher centers of the central nervous system, permitting the brain to coordinate different behaviors either simultaneously or in series.

The stretching of just one muscle, the quadriceps, activates several hundred sensory neurons, each of which makes direct contact with 45 to 50 motor neurons. This pattern of connection, in which one neuron activates many target cells, is called divergence (Figure 2–7A). It is especially common in the input stages of the nervous system; by distributing its signals to many target cells, a single neuron can exert wide and diverse influence. Conversely, a single motor cell in the knee jerk circuit receives 200 to 450 input contacts from approximately 130 sensory cells. This pattern of connection is called *convergence* (Figure 2–7B). It is common at the output stages of the nervous system; a target motor cell that receives information from many sensory neurons is able to integrate information from many sources. Convergence also ensures that a motor neuron is activated only if a sufficient number of sensory neurons become activated together.

A stretch reflex such as the knee-jerk reflex is a simple behavior produced by two classes of neurons

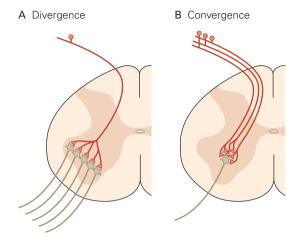

Figure 2–7 Diverging and converging neuronal connections are a key organizational feature of the brain.

A. In the sensory systems each receptor neuron usually contacts several neurons that represent the second stage of processing. At subsequent processing stages the incoming connections diverge even more. This allows sensory information from a single site to be distributed more widely in the spinal cord and brain.

B. By contrast, motor neurons are the targets of progressively converging connections. With this arrangement input from many presynaptic cells is required to activate the motor neuron.

connecting at excitatory synapses. But not all important signals in the brain are excitatory. Many neurons produce inhibitory signals that reduce the likelihood of firing. Even in the simple knee-jerk reflex the sensory neurons make both excitatory and inhibitory connections. Excitatory connections in the leg's extensor muscles cause these muscles to contract, whereas connections with inhibitory interneurons prevent the antagonist flexor muscles from contracting. This feature of the circuit is an example of *feed-forward inhibition* (Figure 2–8A). In the knee-jerk reflex, feed-forward inhibition is *reciprocal*, ensuring that the flexor and extensor pathways always inhibit each other so that only muscles appropriate for the movement and not those opposed to it are recruited.

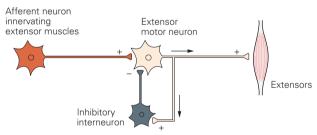

Neurons can also have connections that provide *feedback inhibition*. For example, a motor neuron may have excitatory connections with both a muscle and an inhibitory interneuron that in turn inhibits the motor neuron. The inhibitory interneuron is thus able to limit the ability of the motor neuron to excite the muscle (Figure 2–8B). We will encounter many examples of feed-forward and feedback inhibition when we examine more complex behaviors in later chapters.

Signaling Is Organized in the Same Way in All Nerve Cells

To produce a behavior, a stretch reflex for example, each participating sensory and motor nerve cell must generate four different signals in sequence, each at different site within the cell: an input signal, a trigger signal, a conducting signal, and an output signal. Regardless of cell size and shape, transmitter biochemistry, or behavioral function, almost all neurons can be described by a model neuron that has four functional

A Feed-forward inhibition Afferent neurons innervating extensor muscles Extensor motor neuron Inhibitory interneuron innervating flexor muscles

B Feedback inhibition

Flexor motor neuron

Flexors

Figure 2–8 Inhibitory interneurons can produce either feed-forward or feedback inhibition.

A. Feed-forward inhibition enhances the effect of the active pathway by suppressing the activity of pathways mediating opposing actions. Feed-forward inhibition is common in monosynaptic reflex systems. For example, in the knee-jerk reflex circuit (Figure 2–6) afferent neurons from extensor muscles excite not only the extensor motor neurons but also inhibitory interneurons that prevent the firing of the motor cells innervating the opposing flexor muscles.

B. Feedback inhibition is a self-regulating mechanism. Here extensor motor neurons act on inhibitory interneurons that in turn act on the extensor motor neurons themselves and thus reduce their probability of firing. The effect is to dampen activity within the stimulated pathway and prevent it from exceeding a certain critical level.

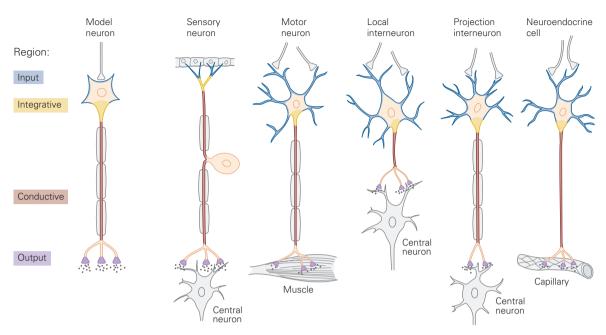

Figure 2–9 Most neurons, regardless of type, have four functional regions in which different types of signals are generated. Thus the functional organization of most neurons can be represented schematically by a model neuron. The input, integrative, and conductive signals are all electrical and integral

to the cell, whereas the output signal is a chemical substance ejected by the cell into the synaptic cleft. Not all neurons share all these features; for example, local interneurons often lack a conductive component.

components that generate the four types of signals: a receptive component, a summing or integrative component, a long-range signaling component, and a secretory component (Figure 2–9). This model neuron is the physiological expression of Ramón y Cajal's principle of dynamic polarization.

The different types of signals generated in a neuron are determined in part by the electrical properties of the cell membrane. Every cell, including a neuron, maintains a certain difference in the electrical potential on either side of the plasma membrane when the cell is at rest. This is called the resting membrane potential. In a typical resting neuron the voltage of the inside of the cell is about 65 mV more negative than the voltage outside the cell. Because the voltage outside the membrane is defined as zero, we say the resting membrane potential is -65 mV. The resting potential in different nerve cells ranges from -40 to -80 mV; in muscle cells it is greater still, about -90 mV. As we shall see in Chapter 6, the resting membrane potential results from two factors: the unequal distribution of electrically charged ions, in particular the positively charged Na⁺ and K⁺ ions, and the selective permeability of the membrane.

The unequal distribution of positively charged ions on either side of the cell membrane is maintained

by two main mechanisms. Intracellular Na^+ and K^+ concentrations are largely controlled by a membrane protein that actively pumps Na^+ out of the cell and K^+ back into it. This Na^+-K^+ pump, about which we shall learn more in Chapter 6, keeps the Na^+ concentration in the cell low (about one-tenth the concentration outside the cell) and the K^+ concentration high (about 20 times the concentration outside). The extracellular concentrations of Na^+ and K^+ are maintained by the kidneys.

The cell membrane is selectively permeable to K⁺ because the otherwise impermeable membrane contains proteins that form pores called *ion channels*. The channels that are active when the cell is at rest are highly permeable to K⁺ but considerably less permeable to Na⁺. The K⁺ ions tend to leak out of these open channels, down the ion's concentration gradient. As K⁺ ions exit the cell, they leave behind a cloud of unneutralized negative charge on the inner surface of the membrane, so that the net charge inside the membrane is more negative than that outside.

A cell, such as nerve and muscle, is said to be excitable when its membrane potential can be quickly and significantly altered. This change serves as a signaling mechanism. In some neurons reducing the membrane potential by 10 mV (from -65 to -55 mV) makes the

membrane much more permeable to Na⁺ than to K⁺. The resultant influx of positively charged Na⁺ neutralizes the negative charge inside the cell and causes a brief and explosive change in membrane potential to +40 mV. This *action potential* is conducted down the cell's axon to the axon's terminal, where it initiates an elaborate chemical communication with other neurons or muscle cells. The action potential is actively propagated along the axon so that its amplitude does not diminish by the time it reaches the axon terminal. An action potential typically lasts approximately 1 ms, after which the membrane returns to its resting state, with its normal separation of charges and higher permeability to K⁺ than to Na⁺.

We shall learn more about the mechanisms underlying the resting potential and action potential in Chapters 6 to 7. In addition to the long distance signals represented by the action potential, nerve cells also produce local signals—receptor potentials and synaptic potentials—that are not actively propagated and that typically decay within just a few millimeters.

The change in membrane potential that generates long-range and local signals can be either a decrease or an increase from the resting potential. The resting membrane potential therefore provides the baseline on which all signaling occurs. A reduction in membrane potential is called *depolarization*. Because depolarization enhances a cell's ability to generate an action potential, it is excitatory. In contrast, an increase in membrane potential is called *hyperpolarization*. Hyperpolarization makes a cell less likely to generate an action potential and is therefore inhibitory.

The Input Component Produces Graded Local Signals

In most neurons at rest no current flows from one part of the cell to another, so the resting potential is the same throughout. In sensory neurons current flow is typically initiated by a physical stimulus, which activates specialized receptor proteins at the neuron's receptive surface. In our example of the knee-jerk reflex, stretching of the muscle activates specific ion channels that open in response to stretch of the sensory neuron membrane, as we shall learn in Chapter 5. The opening of these channels when the cell is stretched permits the rapid influx of Na⁺ ions into the sensory cell. This ionic current changes the membrane potential, producing a local signal called the *receptor potential*.

The amplitude and duration of a receptor potential depend on the intensity of the muscle stretch: The larger or longer-lasting the stretch, the larger or longer-lasting the resulting receptor potential (Figure 2–10A).

Thus, unlike the action potential, which is all or none, receptor potentials are graded. Most receptor potentials are depolarizing (excitatory). However, hyperpolarizing (inhibitory) receptor potentials are found in the retina.

The receptor potential is the first representation of stretch to be coded in the nervous system. This signal spreads passively, however, and therefore does not travel much farther than 1 to 2 mm. In fact, 1 mm down the axon the amplitude of the signal is only about onethird what it was at the site of generation. To be carried successfully to the central nervous system, the local signal must be amplified—it must generate an action potential. In the knee-jerk reflex the receptor potential in the sensory neuron must reach the first node of Ranvier in the axon. If it is large enough, the signal triggers an action potential that then propagates without failure to the axon terminals in the spinal cord (Figure 2–10C). At the synapse between the sensory neuron and a motor neuron, the action potential produces a chain of events that results in an input signal to the motor neuron.

In the knee-jerk reflex the action potential in the presynaptic terminal of the sensory neuron initiates the release of a chemical substance, or neurotransmitter, into the synaptic cleft (Figure 2–10D). After diffusing across the cleft, the transmitter binds to receptor proteins in the postsynaptic membrane of the motor neuron, thereby directly or indirectly opening ion channels. The ensuing flow of current alters the membrane potential of the motor cell, a change called the *synaptic potential*.

Like the receptor potential, the synaptic potential is graded; its amplitude depends on how much transmitter is released. In the same cell the synaptic potential can be either depolarizing or hyperpolarizing depending on the type of receptor molecule that is activated. Synaptic potentials, like receptor potentials, spread passively and thus are local changes in potential unless the signal reaches beyond the axon's initial segment and thus can give rise to an action potential. The features of receptor and synaptic potentials are summarized in Table 2–1.

The Trigger Zone Makes the Decision to Generate an Action Potential

Sherrington first pointed out that the function of the nervous system is to weigh the consequences of different types of information and then decide on appropriate responses. This *integrative* function of the nervous system is clearly seen in the actions of the trigger zone of the neuron, the initial segment of the axon.

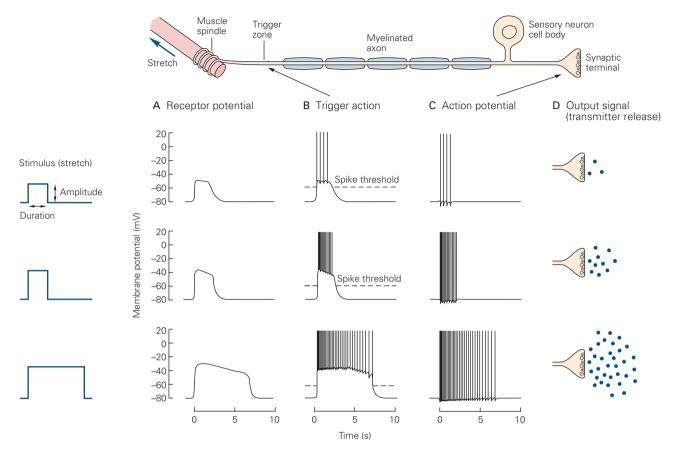

Figure 2–10 Each of the neuron's four signaling components produces a characteristic signal. The figure shows a sensory neuron activated by stretching of a muscle, which the neuron senses through a specialized receptor, the muscle spindle.

A. The input signal, called a receptor potential, is graded in amplitude and duration, proportional to the amplitude and duration of the stimulus.

B. The trigger zone sums the depolarization generated by the receptor potential. An action potential is generated only if the receptor potential exceeds a certain voltage threshold. Once this threshold is surpassed, any further increase in amplitude of the receptor potential can only increase the frequency with which the action potentials are generated, because action potentials have a constant amplitude. The duration of the

receptor potential determines the duration of the train of action potentials. Thus the graded amplitude and duration of the receptor potential is translated into a frequency code in the action potentials generated at the trigger zone. All action potentials produced are propagated faithfully along the axon.

C. Action potentials are all-or-none. Because all action potentials have a similar amplitude and duration, the frequency and duration of firing represents the information carried by the signal.

D. When the action potential reaches the synaptic terminal, it initiates the release of a neurotransmitter, the chemical substance that serves as the output signal. The frequency of action potentials determines exactly how much neurotransmitter is released by the cell.

Action potentials are generated by a sudden influx of Na⁺ through channels in the cell membrane that open and close in response to changes in membrane potential. When an input signal (a receptor potential or synaptic potential) depolarizes an area of membrane, the local change in membrane potential opens local Na⁺ channels that allow Na⁺ to flow down its concentration gradient, from outside the cell where the Na⁺ concentration is high to inside where it is low.

Because the initial segment of the axon has the highest density of voltage-sensitive Na⁺ channels and therefore the lowest threshold for generating an action potential, an input signal spreading passively along the cell membrane is more likely to give rise to an action potential at the initial segment than at other sites in the cell. This part of the axon is therefore known as the *trigger zone*. It is here that the activity of all receptor (or synaptic) potentials is summed and where, if the

Signal type	Amplitude (mV)	Duration	Summation	Effect of signal	Type of propagation
Local (passive) signals					
Receptor potentials	Small (0.1–10)	Brief (5–100 ms)	Graded	Hyperpolarizing or depolarizing	Passive
Synaptic potentials	Small (0.1–10)	Brief to long (5 ms–20 min)	Graded	Hyperpolarizing or depolarizing	Passive
Propagated (active) signals					
Action potentials	Large (70–110)	Brief (1–10 ms)	All-or-none	Depolarizing	Active

Table 2-1 Comparison of Local (Passive) and Propagated Signals

sum of the input signals reaches threshold, the neuron generates an action potential.

The Conductive Component Propagates an All-or-None Action Potential

The action potential is all-or-none: Stimuli below the threshold do not produce a signal, but stimuli above the threshold all produce the signals of the same amplitude. However much the stimuli vary in intensity or duration, the amplitude and duration of each action potential are pretty much the same. In addition, unlike receptor and synaptic potentials, which spread passively and decrease in amplitude, the action potential does not decay as it travels along the axon to its target—a distance that can be as great as 2 m—because it is periodically regenerated. This conducting signal can travel at rates as fast as 100 m/s.

The remarkable feature of action potentials is that they are highly stereotyped, varying only subtly (but in some cases importantly) from one nerve cell to another. This feature was demonstrated in the 1920s by Edgar Adrian, one of the first to study the nervous system at the cellular level. Adrian found that all action potentials have a similar shape or wave-form (see Figure 2–2). Indeed, the action potentials carried into the nervous system by a sensory axon often are indistinguishable from those carried out of the nervous system to the muscles by a motor axon.

Only two features of the conducting signal convey information: the number of action potentials and the time intervals between them (Figure 2–10C). As Adrian put it in 1928, summarizing his work on sensory fibers: "all impulses are very much alike, whether the message is destined to arouse the sensation of light,

of touch, or of pain; if they are crowded together the sensation is intense, if they are separated by long intervals the sensation is correspondingly feeble." Thus, what determines the intensity of sensation or speed of movement is the frequency of the action potentials. Likewise, the duration of a sensation or movement is determined by the period over which action potentials are generated.

In addition to the frequency of the action potentials, the pattern of action potentials also conveys important information. For example, some neurons are not silent in the absence of stimulation but are spontaneously active. Some spontaneously active nerve cells (beating neurons) fire action potentials regularly; other neurons (bursting neurons) fire in brief bursts of action potentials. These diverse cells respond differently to the same excitatory synaptic input. An excitatory synaptic potential may initiate one or more action potentials in a cell that does not have a spontaneous activity, but in spontaneously active cells that same input will modulate the rhythm by increasing the rate of firing of action potentials.

An even more dramatic difference is seen when the input signal is inhibitory. Inhibitory inputs have little information value in a silent cell. By contrast, in spontaneously active cells inhibition can have a powerful *sculpting* role. By establishing periods of silence in otherwise ongoing activity, inhibition can produce a complex pattern of alternating firing and silence where none existed. These subtle differences in firing patterns may have important functional consequences for the information transfer between neurons. This has led mathematical modelers of neuronal networks to attempt to delineate neural codes in which information is also carried by the fine-grained pattern of firing—the exact timing of action potentials (Figure 2–11).

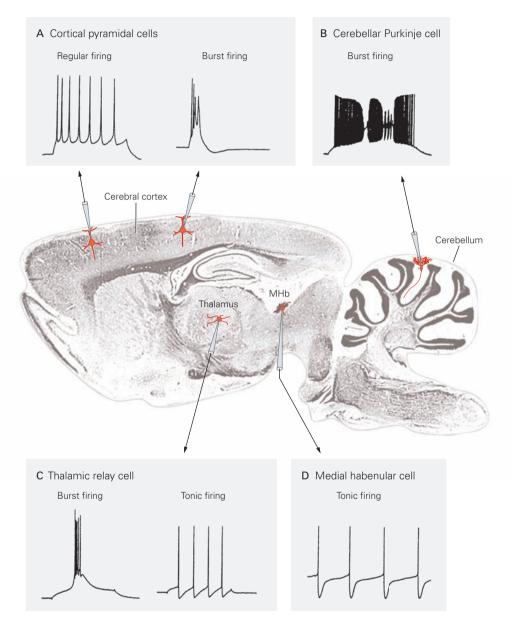

Figure 2–11 Neurons in the mammalian brain exhibit widely varying electrophysiological properties. (Reproduced, with permission, from McCormick, 2004.)

A. Intracellular injection of a depolarizing current pulse in a cortical pyramidal cell results in a train of action potentials that decline in frequency. This pattern of activity is known as regular firing. Some cortical cells generated bursts of three or more action potentials, even when depolarized only for a short period.

B. Cerebellar Purkinje cells generate high-frequency trains of action potentials in their cell bodies that are disrupted by the

generation of Ca^{2+} action potentials in their dendrites. These cells can also generate plateau potentials from the persistent activation of Na^+ conductances.

C. Thalamic relay cells may generate action potentials either as bursts or tonic trains of action potentials owing to the presence of a large low-threshold Ca²⁺ current.

D. Medial habenular cells generate action potentials at a steady and slow rate, in a pacemaker fashion.

If signals are stereotyped and reflect only the most elementary properties of the stimulus, how can they carry the rich variety of information needed for complex behavior? How is a message that carries visual information about a bee distinguished from one that carries pain information about the bee's sting, and how are these sensory signals distinguished from motor signals for voluntary movement? The answer is simple and yet is one of the most important organizational principles of the nervous system: Pathways of connected neurons, not individual neurons, convey information. Interconnected neurons form anatomically and functionally distinct pathways. The neural pathways activated by receptor cells in the retina that respond to light are completely distinct from the pathways activated by sensory cells in the skin that respond to touch.

The Output Component Releases Neurotransmitter

When an action potential reaches a neuron's terminal it stimulates the release of chemical substances from the cell. These substances, called *neurotransmitters*, can be small organic molecules, such as L-glutamate and acetylcholine, or peptides like substance P or LHRH (luteinizing hormone releasing hormone).

Neurotransmitter molecules are held in subcellular organelles called *synaptic vesicles*, which accumulate at specialized release sites in the terminals of the axon called *active zones*. To eject their transmitter substance into the synaptic cleft, the vesicles move up to and fuse with the neuron's plasma membrane, then burst open, a process known as *exocytosis*. The molecular machinery of neurotransmitter release is described in Chapters 11 and 12.

Once released, the neurotransmitter is the neuron's output signal. Like the input signal, it is graded. The amount of transmitter released is determined by the number and frequency of the action potentials that reach the presynaptic terminals (Figure 2–10C,D). After release the transmitter diffuses across the synaptic cleft and binds to receptors on the postsynaptic neuron. This binding causes the postsynaptic cell to generate a synaptic potential. Whether the synaptic potential has an excitatory or inhibitory effect depends on the type of receptor in the postsynaptic cell, not on the particular chemical neurotransmitter. The same transmitter substance can have different effects at different receptors.

The Transformation of the Neural Signal from Sensory to Motor Is Illustrated by the Stretch-Reflex Pathway

We have seen that the properties of a signal are transformed as the signal moves from one component of

a neuron to another or between neurons. This transformative chain of events can be seen in the relay of signals for the stretch reflex.

When a muscle is stretched, the amplitude and duration of the stimulus are reflected in the amplitude and duration of the receptor potential generated in the sensory neuron (Figure 2–12A). If the receptor potential exceeds the threshold for an action potential in that cell, the graded signal is transformed at the trigger zone into an action potential, an all-or-none signal. The more the receptor potential exceeds threshold, the greater the depolarization and consequently the greater the frequency of action potentials in the axon. The duration of the input signal also determines the duration of the train of action potentials.

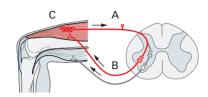

The information encoded by the frequency and duration of firing is faithfully conveyed along the axon to its terminals, where the firing of action potentials determines the amount of transmitter released. These stages of signaling have their counterparts in the motor neuron (Figure 2–12B) and in the muscle (Figure 2–12C).

Nerve Cells Differ Most at the Molecular Level

The model of neuronal signaling we have outlined is a simplification that applies to most neurons but there are some important variations. For example, some neurons do not generate action potentials. These are typically local interneurons without a conductive component; they have no axon or such a short one that regeneration of the signal is not required. In these neurons the input signals are summed and spread passively to the presynaptic terminal region nearby where transmitter is released. Neurons that are spontaneously active do not require sensory or synaptic inputs to fire action potentials because they have a special class of ion channels that permit Na⁺ current flow even in the absence of excitatory synaptic input.

Even cells that are similar morphologically can differ importantly in molecular details. For example, they can have different combinations of ion channels. As we shall learn in Chapter 7, different ion channels provide neurons with various thresholds, excitability properties, and firing patterns (Figure 2–11). Neurons with different ion channels can therefore encode synaptic potentials into different firing patterns and thereby convey different information.

Neurons also differ in the chemical substances they use as transmitters and in the receptors that receive transmitter substances from other neurons. Indeed, many drugs that act on the brain do so by modifying the actions of specific chemical transmitters or receptors.

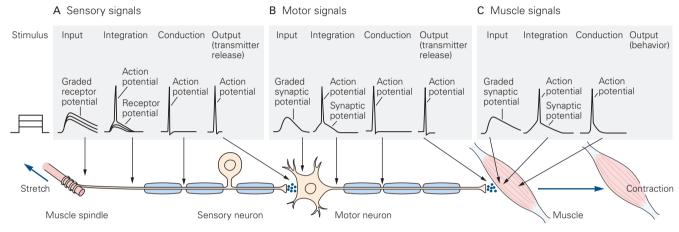

Figure 2–12. The sequence of signals that produces a reflex action.

A. The stretching of a muscle produces a receptor potential in the specialized receptor (the muscle spindle). The amplitude of the receptor potential is proportional to the intensity of the stretch. This potential spreads passively to the integrative or trigger zone at the first node of Ranvier. If the receptor potential is sufficiently large, it triggers an action potential that then propagates actively and without change along the axon to the axon terminal. At specialized sites in the terminal the action potential leads to an output signal, the release of a chemical neurotransmitter. The transmitter diffuses across the synaptic cleft between the axon terminal and a target motor neuron

that innervates the stretched muscle; it then binds to receptor molecules on the external membrane of the motor neuron.

- B. This interaction initiates a synaptic potential that spreads passively to the trigger zone of the motor neuron's axon, where it initiates an action potential that propagates actively to the terminal of the motor neuron's axon. The action potential releases a neuro transmitter where the axon terminal meets a muscle fiber.
- **C.** The neurotransmitter binds receptors on the muscle fiber, triggering a synaptic potential in the muscle. If sufficiently large, or if combined with signals from other motor neurons, the synaptic potential will generate an action potential in the muscle, causing contraction of the muscle fiber.

Because of physiological differences among neurons, a disease may affect one class of neurons but not others. Certain diseases strike only motor neurons (amyotrophic lateral sclerosis and poliomyelitis), whereas others affect primarily sensory neurons (tabes dorsalis, a late stage of syphilis). Parkinson disease, a disorder of voluntary movement, damages a small population of interneurons that use dopamine as a neurotransmitter. Some diseases are selective even within the neuron, affecting only the receptive elements, the cell body, or the axon. In Chapter 14 we describe how research into myasthenia gravis, a disease caused by a faulty transmitter receptor in the muscle membrane, has provided important insights into synaptic transmission. Indeed, because the nervous system has so many cell types and variations at the molecular level, it is susceptible

to more diseases (psychiatric as well as neurological) than any other organ system of the body.

Despite the differences among nerve cells, the basic mechanisms of electrical signaling are surprisingly similar. This simplicity is fortunate, for understanding the molecular mechanisms of signaling in one kind of nerve cell aids the understanding of these mechanisms in many other nerve cells.

Neural Network Models Simulate the Brain's Parallel Processing of Information

The stretch reflex illustrates how interactions between just a few types of nerve cells can constitute a functional circuit that produces a simple behavior, even though the number of neurons involved is large (the stretch reflex circuit has perhaps a few hundred sensory neurons and a hundred motor neurons). Can the individual neurons implicated in a complex behavior be identified with the same precision?

In invertebrate animals, and in some lower-order vertebrates, a single cell (a so-called command cell) can initiate a complex behavioral sequence. But as far as we know no complex human behavior is initiated by a single neuron. Rather, each behavior is generated by the actions of many cells. Broadly speaking, as we have seen, there are three components of the neural control of behavior: sensory input, intermediate processing, and motor output. In vertebrates each component is likely to be mediated by a single group or several distinct groups of neurons.

Moreover, each component may have multiple neural pathways that simultaneously provide the same or similar information. The deployment of several neuronal groups or pathways to convey similar information is called *parallel processing*. Parallel processing also occurs in a single pathway when different neurons in the pathway perform similar computations simultaneously. Parallel processing makes enormous sense as an evolutionary strategy for building a more powerful brain, for it increases both the speed and reliability of function within the central nervous system.

The importance of abundant, highly specific parallel connections has long been recognized by scientists attempting to construct theoretical models of the brain. The branch of computer science known as artificial intelligence originally used serial processing to simulate the brain's cognitive processes—pattern recognition, learning, memory, and motor performance. These serial models performed many tasks rather well, including playing chess. However, they performed poorly with other computations that the brain does almost instantaneously, such as recognizing faces or comprehending speech.

Many theoretical neurobiologists have turned to different types of models that include parallel processing, which they call *neural networks*. In these models, elements of the system process information simultaneously using both feed-forward and feedback connections. Interestingly, in systems with feedback circuits it is the dynamic activity of the system that determines the outcome of computation, not inputs or initial conditions.

Neural network models capture well the highly recurrent architecture of most actual neural circuits and also the ability of the brain to function in the absence of specific sensory input from outside the body such as during thinking, sleep, and the generation of endogenous rhythms, something with which traditional deterministic models have difficulty. Neural network models also show that analysis of individual elements of a system may not be enough to decode the *action potential code*. According to this neural network view, what makes the brain a remarkable information processing organ is not the complexity of its neurons but the fact that it has many elements interconnected in a variety of complex ways. Neural network modeling is discussed in Appendices E and F.

Neural Connections Can Be Modified by Experience

Most learning results in behavioral changes that endure for years, but even simple reflexes can be modified briefly. The fact that behavior is learned raises an interesting question: How is behavior modified if the nervous system is wired so precisely? How can changes in the neural control of behavior occur when connections between the signaling units, the neurons, are set during early development?

Several solutions for this dilemma have been proposed. The proposal that has proven most farsighted is the *plasticity hypothesis*, first put forward at the turn of the 20th century by Ramón y Cajal. A modern form of this hypothesis was advanced by the Polish psychologist Jerzy Konorski in 1948:

The application of a stimulus leads to changes of a twofold kind in the nervous system . . . [T]he first property, by virtue of which the nerve cells *react* to the incoming impulse . . . we call *excitability*, and . . . changes arising . . . because of this property we shall call *changes due to excitability*. The second property, by virtue of which certain permanent functional transformations arise in particular systems of neurons as a result of appropriate stimuli or their combination, we shall call *plasticity* and the corresponding changes *plastic changes*.

There is now considerable evidence for functional plasticity at chemical synapses. These synapses often have a remarkable capacity for short-term physiological changes (lasting seconds to hours) that increase or decrease synaptic effectiveness. Long-term changes (lasting days) can give rise to further physiological changes that lead to anatomical alterations, including pruning of preexisting synapses and even growth of new ones.

As we shall see in later chapters, chemical synapses are functionally and anatomically modified through experience and learning as much as during early development. Functional alterations, physiological changes, are typically short-term and result in changes in the effectiveness of existing synaptic connections.

Anatomical alterations are typically long-term and consist of the growth of new synaptic connections between neurons. It is this functional plasticity of neurons that endows each of us with our individuality.

Glossary

LL BEHAVIORS ARE SHAPED BY THE interplay of genes and the environment. The most stere-otypic behaviors of simple animals are influenced by the environment, and the highly evolved behaviors of humans are constrained by innate properties specified by genes. Genes do not control behavior directly, but the RNAs and proteins encoded by genes act at different times and at many levels to affect the brain. Genes specify the developmental programs that assemble the brain and are essential to the properties of neurons and synapses that allow neuronal circuits to function. Genes that are stably inherited over generations create the machinery that allows new experiences to change the brain during learning.

In this chapter we ask how genes contribute to behavior. We begin with an overview of the evidence that genes do influence behavior, and then review basic principles of molecular biology and genetic transmission. We then provide a few examples of the way that genetic influences on behavior have been documented. Many persuasive links between genes and human behavior have emerged from the analysis of human brain development and function. However, a deep understanding of the ways that genes regulate behavior has emerged primarily from studies of worms, flies, and mice, animals whose genomes are accessible to experimental manipulation. Despite formidable challenges in studying complex genetic traits in humans, recent progress has revealed the genetic basis of some developmental and psychiatric disorders, and holds the promise of future understanding.

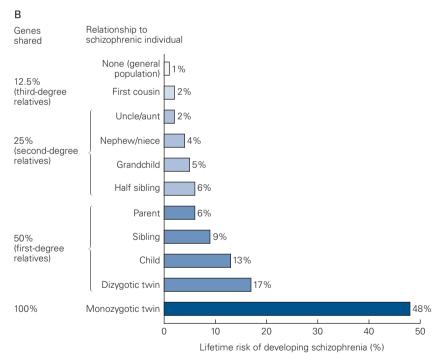

Figure 3–1 Familial risk of psychiatric disorders provides evidence of heritability.

A. Correlations between monozygotic twins for psychiatric disorders are considerably greater than those between dizygotic twins. Monozygotic twins share nearly all genes and have a high (but not 100%) risk of sharing the disease state. Dizygotic twins share 50% of their genetic material. A score of zero represents no correlation (the average result for two random people), whereas a score of 1.0 represents a perfect correlation. (Adapted, with permission, from McGue and Bouchard 1998.)

B. The risk of developing schizophrenia is greater in close relatives of a schizophrenic patient. Like dizygotic twins, parents and children, as well as brothers and sisters, share 50% of their genetic material. If only a single gene accounted for schizophrenia, the risk should be the same for parents, siblings, children, and dizygotic twins of patients. The variation between family members shows that more complex genetic and environmental factors are in play. (Modified, with permission, from Gottesman 1991.)

Genes, Genetic Analysis, and Heritability in Behavior

Many human psychiatric disorders and neurological diseases have a genetic component. The relatives of a patient are more likely than the general population to have the disease. The extent to which genetic factors account for traits in a population is called heritability. The strongest case for heritability is based on twin studies, first used by Francis Galton in 1883. Identical twins develop from a single fertilized egg that splits into two soon after fertilization; such monozygotic twins share all genes. In contrast, fraternal twins develop from two different fertilized eggs; these dizygotic twins, like normal siblings, share on average half their genetic information. Systematic comparisons over many years have shown that identical twins tend to be more similar (concordant) for neurological and psychiatric traits than fraternal twins, providing evidence of a heritable component of these traits (Figure 3–1A).

In an extension of the twin study model, Thomas Bouchard and colleagues in the Minnesota Twin Study examined identical twins that were separated early in life and raised in different households. Despite sometimes great differences in their environment, twins shared predispositions for the same psychiatric disorders and even tended to share personality traits, like extraversion. Thus genetic variation contributes to normal human differences, not just to disease states.

Heritability for human diseases and behavioral traits is usually substantially less than 100%, demonstrating that the environment is an important factor in acquiring diseases or traits. Estimates of heritability for many neurological, psychiatric, and behavioral traits from twin studies range around 50%, but heritability can be higher or lower for particular traits (Figure 3–1B). Although studies of identical twins and other kinships provide support for the idea that human behavior has a hereditary component, they do not tell us which genes are important, let alone how specific genes affect behavior. These questions can be addressed more easily by genetic studies in experimental animals in which both the gene and the environment are strictly controlled.

The Nature of the Gene

The related scientific areas of molecular biology and transmission genetics are central to our modern understanding of genes. The following primer introduces these ideas; a glossary at the end of the chapter defines commonly used terms.

Genes are made of DNA, and it is DNA that is passed on from one generation to the next. Through DNA replication exact copies of each gene are provided to all cells in an organism as well as to succeeding generations. DNA is made of two strands, each of which has a deoxyribose-phosphate backbone attached to a series of four subunits: the nucleotides adenine (A), guanine (G), thymine (T), and cytosine (C). The two strands are paired so that an A on one strand is always paired with a T on the complementary strand, and a G with a C (Figure 3–2). This complementarity ensures accurate copying of DNA during DNA replication and drives transcription of DNA into RNA. RNA differs from DNA in that it is single-stranded, has a ribose rather than a deoxyribose backbone, and uses the nucleoside base uridine (U) in the place of thymine.

Most genes encode protein products, which are generated by *translation* of the linear messenger RNA (mRNA) sequence into a linear polypeptide (protein) sequence composed of 20 different amino acids. A typical gene consists of a coding region, which is translated into a protein, and noncoding regions (Figure 3–3). The coding region is usually broken into small segments called *exons* that are separated by noncoding stretches called *introns*. The introns are deleted from the mRNA before its translation into protein.

Some functional RNAs do not encode protein. These include ribosomal RNAs (rRNAs) and transfer RNAs (tRNAs), essential components of the machinery for mRNA translation; small nuclear RNAs (snRNAs), which guide mRNA splicing; and microRNAs (miRNAs), small RNAs that pair with complementary sequences in specific mRNAs to inhibit their translation.

Each cell in the body contains the DNA for every gene but only expresses a specific subset of the genes as RNAs. The part of the gene that is transcribed into RNA is flanked by noncoding DNA regions, called *promoters* and *enhancers*, that allow accurate expression of the RNA in the right cells at the right time. Promoters and enhancers are typically found close to the beginning of the region to be transcribed, but can also act at a distance. A unique complement of DNA-binding proteins within each cell interacts with promoters and enhancers to regulate gene expression and resulting cellular properties.

The brain expresses a greater number of genes than any other organ in the body, and within the brain diverse populations of neurons express different groups of genes. The selective gene expression controlled by promoters, enhancers, and the DNA-binding proteins that interact with them permits a fixed number of genes to generate a vastly larger number of neuronal cell types and connections in the brain.

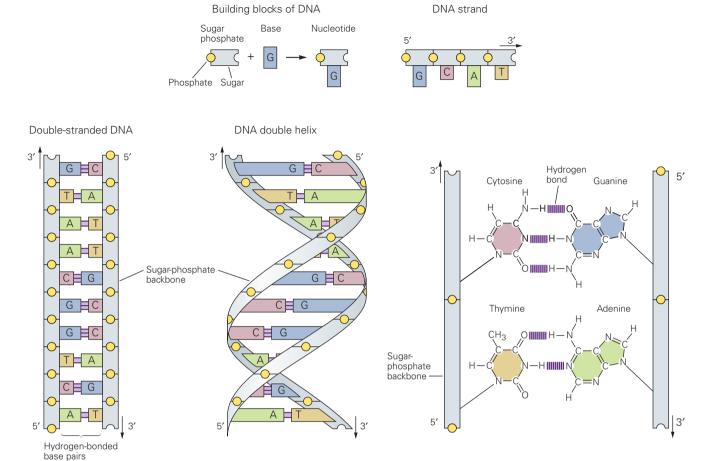

Figure 3–2 Structure of DNA. Four different nucleotide bases, adenine (A), thymine (T), cytosine (C), and guanine

(G), are assembled on a sugar phosphate backbone in the double-stranded DNA helix.

Although genes specify the initial development and properties of the nervous system, the experience of an individual and the resulting activity in specific neural circuits can itself alter the expression of genes. In this way environmental influences are incorporated into the structure and function of neural circuits. The goal of genetics is to unravel the ways that individual genes affect a biological process, the ways that networks of genes affect each other's activity, and the ways that genes interact with the environment.

Genes Are Arranged on Chromosomes

The genes in a cell are arranged in an orderly fashion on long, linear stretches of DNA called *chromosomes*. Each gene in the human genome is reproducibly located at a characteristic position (locus) on a specific chromosome, and this genetic "address" can be used to associate biological traits with a gene's effects. Most multicellular animals (including worms, fruit flies, mice, and humans) are *diploid*; every somatic cell carries two complete sets of chromosomes, one from the mother and the other from the father.

Humans have about 25,000 genes but only 46 chromosomes: 22 pairs of autosomes (chromosomes that are present in both males and females) and 2 sex chromosomes (2 X chromosomes in females, 1 X and 1 Y chromosome in males) (Figure 3–4). Each parent supplies one copy of each autosome to the diploid offspring. Each parent also supplies one X chromosome to female (XX) offspring, but XY males inherit their single X chromosome from their mothers and their single Y chromosome from their fathers. Sex-linked inheritance was discovered in fruit flies by Thomas Hunt Morgan in 1910. This pattern of sex-linked inheritance

associated with the single X chromosome has been highly significant in human genetic studies, where certain X-linked genetic diseases are commonly observed only in males but are genetically transmitted from mothers to their sons.

In addition to the genes on chromosomes, a very small number of an organism's genes are transmitted through cytoplasmic organelles called *mitochondria*, which carry out metabolic processes. Mitochondria in all children come from the ovum and therefore are transmitted from the mother to the child. Certain human disorders, including some neuromuscular degenerative diseases, mental retardation, and some forms of deafness, are caused by mutations in the mitochondrial DNA.

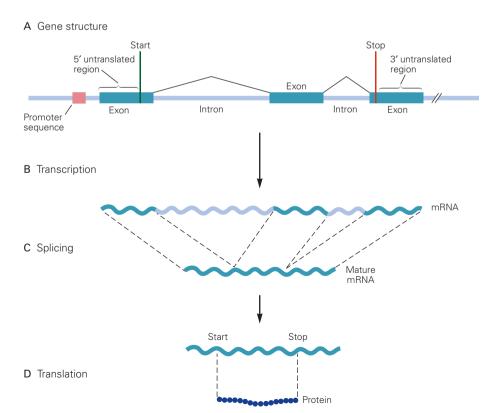

The Relationship Between Genotype and Phenotype

Because an individual has two copies of each autosomal gene, it is important to distinguish the *genotype* of an organism (its genetic makeup) and the *phenotype* (its appearance). The two copies of a particular autosomal gene in an individual are called *alleles*. If the two alleles are identical, the individual is said to be homozygous at that locus. If the alleles vary because of mutations, the individual is heterozygous at that locus. Males are hemizygous for genes on the X chromosome. A population can have a large number of alleles of a gene; for example, a single gene that affects human eye color called OCA2 can have alleles that encode shades of blue, green, hazel, or brown. In the broad sense a genotype is the entire set of alleles forming the genome of an individual; in the narrow sense it is the specific alleles of one gene. By contrast, a phenotype is a description of a whole organism, and is a result of the expression of the organism's genotype in a particular environment.

The difference between genotype and phenotype is evident when considering the consequences of having one normal (wild-type) allele and one mutant allele of the same gene. Most proteins are able to function even if only half their wild-type levels are present, so inactivating one copy of most genes does not lead to a change in phenotype. Thus, two organisms with different genotypes (two wild-type alleles, or one wild-type and one mutant allele) can have the same phenotype. The organism with two mutant alleles has a different phenotype. The phenotype of an animal can change over its lifetime,

Figure 3–3 Gene structure and expression.

- A. A gene consists of coding regions (exons) separated by noncoding regions (introns). Its transcription is regulated by noncoding regions such as promoters and enhancers that are frequently found near the beginning of the gene.
- B. Transcription leads to production of a primary single-stranded RNA transcript that includes both exons and introns.
- C. Splicing removes introns from the immature transcript and ligates the exons into a mature messenger RNA (mRNA), which is exported from the nucleus of the cell.
- **D.** The mature mRNA is translated into a protein product.

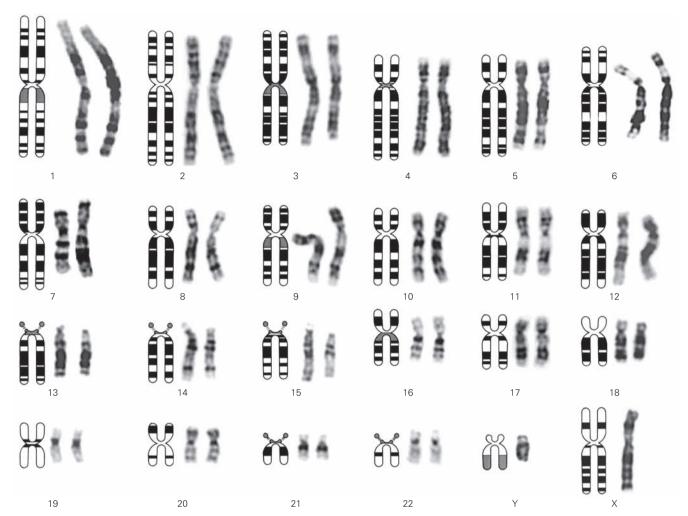

Figure 3–4 Map of normal human chromosomes at metaphase illustrating the distinctive morphology of each chromosome. Characteristic sizes and characteristic light and

dark regions allow chromosomes to be distinguished from one another. (Adapted, with permission, from Watson et al. 1983.)

whereas the genotype remains constant (except for sporadic mutations in cancer cells and DNA rearrangements in the immune system).

If a mutant phenotype is expressed only when both alleles of a gene are mutated (that is, only individuals homozygous for the mutant allele exhibit the phenotype) the phenotypic trait as well as the mutant allele are said to be *recessive*. Recessive mutations usually result from loss or reduction of a functional protein. Recessive inheritance of mutant traits is commonly observed in humans and experimental animals.

If a mutant phenotype results from a combination of one mutant and one wild-type allele, the phenotypic trait and mutant allele are said to be *dominant*.

In general, dominant mutations are more rare than recessive mutations. Some mutations are dominant because 50% of the gene product is not enough for a normal phenotype. Other dominant mutations lead to the production of an abnormal protein by the mutant gene or to expression of the wild-type gene product at an inappropriate time or place.

Genes and proteins are resilient in the face of small changes, so not every sequence change in a gene is deleterious. Most mutations are simply allelic polymorphisms that are silent; that is, they do not have any effect on the phenotype. Some are not silent but are expressed in ways that are benign, for example in eye color. Only rare mutations cause disturbance in

Box 3-1 Mutation: The Origin of Genetic Diversity

Although DNA replication generally is carried out with high fidelity, spontaneous errors called *mutations* do occur. Mutations can result from damage to the purine and pyrimidine bases in DNA, mistakes during the DNA replication process, and recombinations that occur during meiosis. It is these mutations that give rise to genetic polymorphisms.

The rate of spontaneously occurring mutations is low but measurable; spontaneous mutations make a significant contribution to human genetic disease. The frequency of mutations greatly increases when the organism is exposed to chemical mutagens or ionizing radiation during experimental genetic studies.

Chemical mutagens tend to induce *point mutations* involving changes in a single DNA base pair or the deletion of a few base pairs. By contrast, ionizing radiation can induce large insertions, deletions, or translocations. Both spontaneous and induced mutations can lead to changes in the structure of the protein encoded by the gene or to a partial decrease or absence of gene expression.

Functional changes in a single base pair within a coding region can be of three kinds: (1) a *missense mutation*,

where the point mutation results in one amino acid in a protein being substituted for another; (2) a *nonsense mutation*, where a codon (a triplet of nucleotides) within the coding region is replaced by a stop codon, resulting in a shortened (truncated) protein product; or (3) a *frame-shift mutation*, in which small insertions or deletions of nucleotides change the reading frame, leading to the production of a truncated or abnormal protein.

Large-scale mutations involve changes in chromosome structure that can affect the function of one gene or many contiguous genes. Such mutations include rearrangement of genes without the addition or deletion of material (*inversion*), or deletion or duplication of genes in a chromosome (*copy number variation*).

Although most single-gene traits are recessive, rearrangements that lead to duplication or deletion of multiple genes often have dominant effects. For example, individuals with three copies of chromosome 21 have Down syndrome due to the increased expression of multiple genes; no single gene when present in three copies is known to cause the cognitive and physical manifestations of Down syndrome.

development, cell function, or overt behavior. Some mutations are pathogenic, however, and these lead to disease (Box 3–1).

Genes Are Conserved Through Evolution

The nearly complete nucleotide sequence of the human genome was reported in 2000, and the complete nucleotide sequences of many animal genomes have also been decoded. Comparisons between these genomes leads to a surprising conclusion: the unique human species did not result from the invention of unique new human genes.

Humans and chimpanzees are profoundly different in their biology and behavior, yet they share 99% of their protein-coding genes. Moreover, most of the approximately 25,000 genes in humans are also present in other mammals like mice, and over half of all human genes are very similar to genes in invertebrates such as worms and flies (Figure 3–5). The conclusion from this surprising discovery is that ancient genes that humans

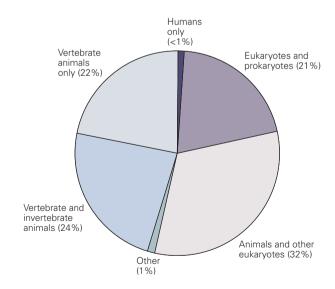

Figure 3–5 Most human genes are related to genes in other species. Less than 1% of genes are specific to humans; other genes may be shared by all living things, by all eukaryotes, by animals only, or by vertebrate animals only. (Modified, with permission, from Lander et al. 2001.)

share with other animals are regulated in new ways to produce novel human properties, like the capacity to generate complex thoughts and language.

Because of this conservation of genes throughout evolution, insights from studies of one animal can often be applied to other animals with related genes, an important fact as animal experiments are often possible when experiments on humans are not. For example, a gene from a mouse that encodes an amino acid sequence similar to a human gene usually has a similar function to the *orthologous* human gene.

Approximately one-half of the human genes have functions that have been demonstrated or inferred from orthologous genes in other organisms (Figure 3–6). A set of genes shared by humans, flies, and even unicellular yeasts encodes the proteins for intermediary metabolism, synthesis of DNA, RNA, and protein, cell division, and for cytoskeletal structures, protein transport, and secretion.

The evolution from single-celled organism to multicellular animals was accompanied by an expansion of genes concerned with intercellular signaling and gene regulation. The genomes of multicellular animals, such as worms, flies, mice, and humans, typically encode thousands of transmembrane receptors, many more than are present in unicellular organisms. These transmembrane receptors are used in cell-to-cell communication in development, in signaling between neurons, and as sensors of environmental stimuli. The genome of a multicellular animal also encodes 1,000 or

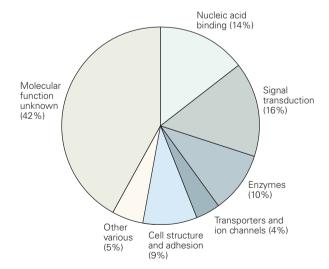

Figure 3–6 The predicted molecular functions of 26,383 human genes. (Modified, with permission, from Venter et al. 2001.)

more different DNA-binding proteins that regulate the expression of other genes. Many of the transmembrane receptors and DNA-binding proteins in humans are related to specific orthologous genes in other vertebrates and invertebrates. By enumerating the shared genetic heritage of the animals, we can infer that the basic molecular pathways for neuronal development, neurotransmission, electrical excitability, and gene expression were present in the common ancestor of worms, flies, mice, and humans. Moreover, studies of animal and human genes have demonstrated that the most important genes in the human brain are those that are most conserved throughout animal phylogeny. Differences between mammalian genes and their invertebrate counterparts most often result from gene duplication in mammals or subtle changes in gene expression and function, rather than the creation of entirely new genes.

The Role of Genes in Behavior Can Be Studied in Animal Models

Because of the conservation between human and animal genes, the relationships between the genes, proteins, and neural circuits that underlie behavior can be studied in animal models that are experimentally tractable. Two important strategies have been applied with great success in the study of gene function.

In classical genetic analysis organisms are first subjected to mutagenesis with a chemical or irradiation that induces random mutations, and then screened for heritable changes that affect the behavior of interest, say, sleep. This approach does not impose a bias as to the kind of gene involved; it is a random search of all possible mutations that cause detectable changes. Genetic tracing of heritable changes allows the identification of the individual genes that are altered in the mutant organism. Thus the pathway of discovery in classical genetics moves from phenotype to genotype, from organism to gene. In reverse genetics a specific gene of interest is targeted for alteration, a genetically modified animal is produced, and the animals with these altered genes are studied. This strategy is both focused and biased—one begins with a candidate gene—and the pathway of discovery moves from genotype to phenotype, from gene to organism.

These two experimental strategies and their more subtle variations form the basis of experimental genetics. Gene manipulation by classical and reverse genetics is conducted in experimental animals, not in humans

Circadian Rhythm Is Generated by a Transcriptional Oscillator in Flies, Mice, and Humans

The first large-scale studies of the influence of genes on behavior were initiated by Seymour Benzer and his colleagues around 1970. They used random mutagenesis and classical genetic analysis to identify mutations that affected learned and innate behaviors in the fruit fly *Drosophila melanogaster*: circadian (daily) rhythms, courtship behavior, movement, visual perception, and memory (Boxes 3–2 and 3–3). These induced mutations have had an immense influence on our understanding of the role of genes in behavior.

We have a particularly complete picture of the genetic basis of the circadian control of behavior. An animal's circadian rhythm couples certain behaviors to a 24-hour cycle linked to the rising and setting of the sun. The core of circadian regulation is an intrinsic biological clock that oscillates over a 24-hour cycle. Because of the intrinsic periodicity of the clock, circadian behavior persists even in the absence of light or other environmental influences.

The clock can be reset, so that changes in the daynight cycle eventually result in a matching shift in the intrinsic oscillator, a phenomenon that is familiar to any traveler recovering from jet lag. Light-driven signals are transmitted by the eye to the brain to reset the clock. Finally, the clock drives output pathways for specific behaviors, such as sleep and locomotion.

Benzer's group searched through thousands of mutant flies to look for rare flies that failed to follow circadian rhythms because of mutations in the genes that direct circadian oscillation. From this work emerged the first insight into the molecular machinery of the circadian clock. Mutations in the *period*, or *per*, gene affected all circadian behaviors generated by the fly's internal clock.

Interestingly, *per* mutations could change the circadian clock in several ways (Figure 3–9). Arrhythmic *per* mutant flies, which exhibited no discernible intrinsic rhythms in any behavior, lacked all function of the *per* gene, so *per* is essential for rhythmic behavior. *Per* mutations that maintained some function of the gene resulted in abnormal rhythms. Long-day alleles produced 28-hour behavioral cycles, whereas short-day alleles produced a 19-hour cycle. Thus *per* is not just an essential piece of the clock, it is actually a timekeeper whose activity can change the rate at which the clock runs.

The *per* mutant has no major adverse effects other than the change in circadian behavior. This observation is important because, prior to the discovery of *per*, many had questioned whether there could be true "behavior genes" that were not required for the other

physiological needs of an animal. *Per* does seem to be such a "behavior gene."

How does *per* keep time? The protein product PER is a transcriptional regulator that affects the expression of other genes. Levels of PER are regulated throughout the day. Early in the morning PER and its mRNA are low. Over the course of the day the PER mRNA and protein accumulate, reaching peak levels after dusk and during the night. The levels then decrease, falling before the next dawn. These observations provide an answer to the circadian rhythm puzzle—a central regulator appears and disappears throughout the day. But they are also unsatisfying because they only push the question back one step—what makes PER cycle? The answer to this question required the discovery of additional clock genes, which were discovered in flies and also in mice.

Emboldened by the success of the fly circadian rhythm screens, Joseph Takahashi began similar but far more labor-intensive genetic screens in mice in the 1990s. He screened hundreds of mutant mice for the rare mice with alterations in their circadian locomotion period, and found a single gene mutation that he called *clock* (Figure 3–10). When mice homozygous for the clock mutation are transferred to darkness, they initially experience extremely long circadian periods and later a complete loss of circadian rhythmicity. The *clock* gene therefore appears to regulate two fundamental properties of the circadian rhythm: the length of the circadian period and the persistence of rhythmicity in the absence of sensory input. These properties are conceptually identical to the properties of the per gene in flies.

The mouse *clock* gene, like the *per* gene in flies, encodes a transcriptional regulator whose activity oscillates through the day. The mouse CLOCK and fly PER proteins also shared a domain called a *PAS domain*, characteristic of a subset of transcriptional regulators. This observation suggests that the same molecular mechanism—oscillation of PAS-domain transcriptional regulation—controls circadian rhythm in flies and mice.

More significantly, parallel studies of flies and mice showed that similar groups of transcriptional regulators affected the circadian clock in both animals. After the mouse *clock* gene was cloned, a fly circadian rhythm gene was cloned and found to be closely related to mouse *clock*, even more so than *per*. In a different study a mouse gene similar to fly *per* was identified and inactivated by reverse genetics. The mutant mouse had a circadian rhythm defect, like fly *per* mutants. In other words, both flies and mice use both *clock* and *per* genes to control their circadian rhythms. A group of genes, not one gene, are conserved regulators of the circadian clock.

Box 3-2 Generating Mutations in Experimental Animals

Random Mutagenesis in Flies

Genetic analysis of behavior in the fruit fly (*Drosophila*) is carried out on flies in which individual genes have been mutated. Mutations can be made by chemical mutagenesis or by insertional mutagenesis. Chemical mutagenesis, for example with ethyl methanesulfonate (EMS), typically creates random point mutations in genes. Insertional mutagenesis occurs when mobile DNA sequences called *transposable elements* randomly insert themselves into other genes.

The most widely used transposable elements in *Drosophila* are the P elements. P elements may be modified to carry genetic markers for eye color, which makes them easy to track in genetic crosses, and they may also be modified to alter expression of the gene into which they are inserted.

To cause P element transposition, *Drosophila* strains that carry P elements are crossed to those that do not. This genetic cross leads to destabilization and transposition of the P elements in the resulting offspring. The mobilization of the P element causes its transposition into a new location in a random gene.

Chemical mutagenesis and transposable element mutagenesis are *random mutagenesis* strategies that can affect any gene in the genome. Similar random mutagenesis strategies are used to create mutations in the nematode worm *Caenorhabditis elegans*, the zebra fish, and mice.

Targeted Mutagenesis in Mice

Advances in molecular manipulation of mammalian genes have permitted precise replacement of a known normal gene with a mutant version. The process of generating a strain of mutant mice involves two separate manipulations. A gene on a chromosome is replaced by homologous recombination in a special cell line known as embryonic stem cells, and the modified cell line is incorporated into the germ cell population of the embryo.

The gene of interest must first be cloned. The gene is mutated and a selectable marker, usually a drug-resistance gene, is then introduced into the mutated fragment. The altered gene is then introduced into embryonic stem cells, and clones of cells that incorporate the altered gene are isolated. DNA samples of each clone are tested to identify a clone in which the mutated gene has been integrated into the homologous (normal) site, rather than some other random site.

When a suitable clone has been identified, the cells are injected into a mouse embryo at the blastocyst stage

(3 to 4 days after fertilization), when the embryo consists of approximately 100 cells. These embryos are then reintroduced into a female that has been hormonally prepared for implantation and allowed to come to term. The resulting embryos are chimeric mixtures between the stem cell line and the host embryo.

Embryonic stem cells in the mouse have the capability of participating in all aspects of development, including the germline. Thus injected cells can become germ cells and pass on the altered gene to future generations of mice. This technique has been used to generate mutations in various genes crucial to development or function in the nervous system.

Altering Gene Function by RNA Interference

RNA interference takes advantage of the fact that most double-stranded RNAs in eukaryotic cells are targeted for destruction; the whole RNA is destroyed even if only part of it is double-stranded. By artificially causing a selected mRNA to become double-stranded, researchers can activate this process to reduce the mRNA levels for specific genes.

To reduce the function of a gene by RNA interference, small-sequence RNA is introduced that will pair with the endogenous mRNA because of complementarity between the small RNA sequence and the desired mRNA. Small RNA is usually 21 or 22 bases in length, and is known as *small interfering RNA* (siRNA) or *small hairpin RNA* (shRNA).

Pairing of siRNA or shRNA with mRNA leads to destruction of the endogenous mRNA by ribonucleases within the cell. The siRNA can be introduced by direct transfection of RNA into cells, or transgenes can be introduced into cells that drive expression of siRNA or shRNA.

If the complementarity between the siRNA and mRNA is perfect, the mRNA is usually destroyed. If the complementarity is close but not perfect, the translation of the mRNA is arrested. Although siRNAs and shRNAs are experimental tools, endogenous small miRNAs with imperfect matches to mRNAs are emerging as an important regulator of translation in many contexts.

RNA interference has great potential to increase the power of genetic analysis because it can be used on any species where transgenes or double-stranded RNA can be delivered to cells. It should allow researchers to change the activity of genes in animals that are not now used in classical genetic analysis such as long-lived birds and fish, and even primates.

Box 3-3 Introducing Transgenes in Flies and Mice

Genes can be manipulated in mice by injecting DNA into the nucleus of newly fertilized eggs (Figure 3–8). In some of the injected eggs the new gene, or transgene, is incorporated into a random site on one of the chromosomes. Because the embryo is at the one-cell stage, the incorporated gene is replicated and ends up in all (or nearly all) of the animal's cells, including the germline.

Gene incorporation is illustrated with a coat color marker gene rescued by injecting a gene for pigment production into an egg obtained from an albino strain. Mice with patches of pigmented fur indicate successful expression of DNA. The transgene's presence is confirmed by testing a sample of DNA from the injected animals.

A similar approach is used in flies. The DNA to be injected is cloned into a transposable element (P element). When injected into the embryo, the DNA becomes inserted into the DNA of germ cell nuclei. P elements can be engineered to express genes at specific times and in specific cells. Transgenes may be wild-type genes that restore function to a mutant, or *designer genes* that activate other genes in new locations or code for a specifically altered protein.

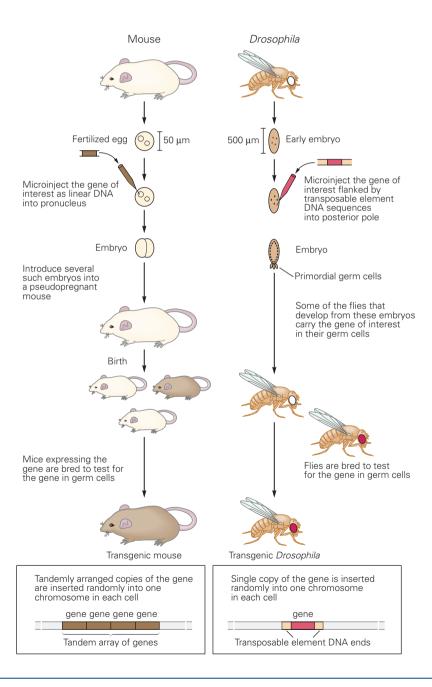

Figure 3–8 Generating transgenic mice and flies. Here the gene injected into the mouse causes a change in coat color, while the gene injected into the fly causes a change in eye color. In some transgenic animals of both species the DNA is inserted at different chromosomal sites in different cells (see illustration at bottom). (Reproduced, with permission, from Alberts et al. 2002.)

Days

Figure 3–9 A single gene governs the circadian rhythms of behaviors in *Drosophila*. Mutations in the *period*, or *per*, gene affect all circadian behaviors regulated by the fly's internal clock. (Reproduced, with permission, from Konopka and Benzer 1971).

A. Locomotor rhythms in normal *Drosophila* and three strains of *per* mutants: short-day, long-day, and arrhythmic. Files were shifted from a cycle of 12 hours of light and 12 hours of dark into continuous darkness, and activity was then monitored under infrared light. Heavy lines indicate activity.

B. Normal adult fly populations emerge from their pupal cases in cyclic fashion, even in constant darkness. The plots show the number of flies (in each of four populations) emerging per hour over a 4-day period of constant darkness. The arrhythmic mutant population emerges without any discernible rhythm.

Characterization of these genes has led to an understanding of the molecular mechanisms of circadian rhythm, and a dramatic demonstration of the similarity of these mechanisms in flies and mice. In both flies and mice the CLOCK protein is a transcriptional activator. Together with a partner protein, it controls the transcription of genes that determine output behaviors such as locomotor activity levels. CLOCK and its partner also stimulate the transcription of the *per* gene. However, PER protein represses CLOCK's ability to stimulate *per* expression, so as PER protein accumulates, *per* transcription falls (Figure 3–11). The 24-hour cycle comes about because

the accumulation and activation of PER protein is delayed by many hours after the transcription of *per*, a result of PER phosphorylation, PER instability, and interactions with other cycling proteins.

Days

The molecular properties of *per, clock,* and related genes generate all properties essential for circadian rhythm. The key elements of the regulatory process are:

- 1. The transcription of circadian rhythm genes varies with the 24-hour cycle: PER activity is high at night, CLOCK activity is high during the day.
- 2. The circadian rhythm genes are transcription factors that affect each other's mRNA level,

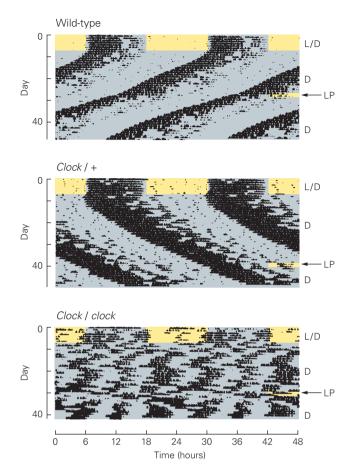

Figure 3–10 Rhythmicity in *clock* mutant mice. The records show periods of locomotor activity by three animals: wild-type, heterozygous, and homozygous. All animals were kept on a light-dark (L/D) cycle of 12 hours for the first 7 days, then transferred to constant darkness (D). They later were exposed to a 6-hour light period (LP) to reset the rhythm. The circadian rhythm for the wild-type mouse has a period of 23.1 hours. The period for the heterozygous *clock/+* mouse is 24.9 hours. The homozygous *clock/clock* mice experience a complete loss of circadian rhythmicity on transfer to constant darkness and transiently express a rhythm of 28.4 hours after the light period. (Reproduced, with permission, from Takahashi et al. 1994.)

generating the oscillations. CLOCK activates *per* transcription and PER represses CLOCK function.

- 3. The circadian rhythm genes also control the transcription of output genes that affect many downstream responses. For example, in flies the neuropeptide gene *pdf* controls locomotor activity levels.
- 4. The oscillation of these genes can be reset by light.

Recent work has shown that the same genetic network controls circadian rhythm in humans. People with

advanced sleep-phase syndrome have short 20-day cycles and an extreme early-to-bed, early-to-rise "morning lark" phenotype. Louis Ptáček and Ying-hui Fu found that these individuals have mutations in a human *per* gene. These results demonstrate that genes for behavior are conserved from insects to humans. Advance sleep-phase syndrome is discussed in detail in the chapter on sleep (see Chapter 51).

Natural Variation in a Protein Kinase Regulates Activity in Flies and Honeybees

In the genetic studies of circadian rhythm described above, random mutagenesis was used to identify genes of interest in a biological process. All normal individuals have functional copies of *per, clock,* and the related genes; only after mutagenesis were different alleles generated. Another, more subtle question about the role of genes in behavior is to ask which genetic changes make normal individuals behave differently from each other. Work by Marla Sokolowski and her colleagues led to the identification of the first gene associated with variation in behavior among normal individuals in a species.

Larvae of *Drosophila* vary in activity level and locomotion. Some larvae, called rovers, move over long distances (Figure 3–12). Others, called sitters, are relatively stationary. *Drosophila* larvae isolated from the wild can be either rovers or sitters, indicating that these are natural variations and not laboratory-induced mutations. These traits are heritable; rover parents have rover offspring and sitter parents have sitter offspring.

Sokolowski used crosses between different wild flies to investigate the genetic differences between rover and sitter larvae. These crosses showed that the difference between rover and sitter larvae lies in a single major gene, the for (forager) locus. The for gene encodes a signal transduction enzyme, a protein kinase activated by the cellular metabolite cyclic guanosine 3'-5'monophosphate (cGMP). Thus this natural variation in behavior arises from altered regulation of signal transduction pathways. Many neuronal functions are regulated by protein kinases such as the cGMP-dependent kinase encoded by the for gene. Molecules such as protein kinases are particularly significant at transforming short-term neural signals into long-term changes in the property of a neuron or circuit.

Why would variability in signaling enzymes be preserved in wild populations of *Drosophila*, which typically include both rovers and sitters? The answer is that variations in the environment favor alternative genetic

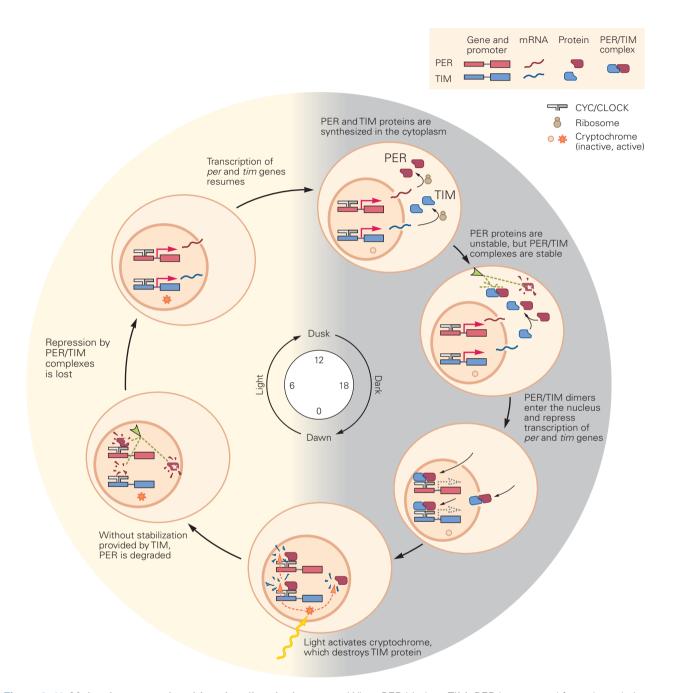

Figure 3–11 Molecular events that drive circadian rhythm. The genes that control the circadian clock are regulated by two nuclear proteins, PER and TIM, that slowly accumulate and then bind to one another to form dimers. When PER and TIM accumulate enough to dimerize, they enter the nucleus and shut off the expression of circadian genes including themselves. They do so by inhibiting CLOCK and CYCLE, which stimulate the transcription of *per* and *tim* genes. PER is highly unstable; most of the protein is degraded so quickly that it never has a chance to repress CLOCK-dependent *per* transcription. The degradation of PER is regulated by at least two different phosphorylation events by different protein kinases.

When PER binds to TIM, PER is protected from degradation. As CLOCK drives more and more *per* and *tim* expression, enough PER and TIM eventually accumulate that the two can bind and stabilize each other, at which point they enter the nucleus to repress their own transcription. As a result, *per* and *tim* mRNA levels fall; thereafter, PER and TIM protein levels fall and CLOCK can (once again) drive expression of *per* and *tim* mRNA. During daylight TIM protein is degraded by signaling pathways that are regulated by light (including cryptochrome), so PER/TIM complexes form only at night. The CLOCK protein induces PER and TIM expression but is inhibited by PER and TIM proteins.

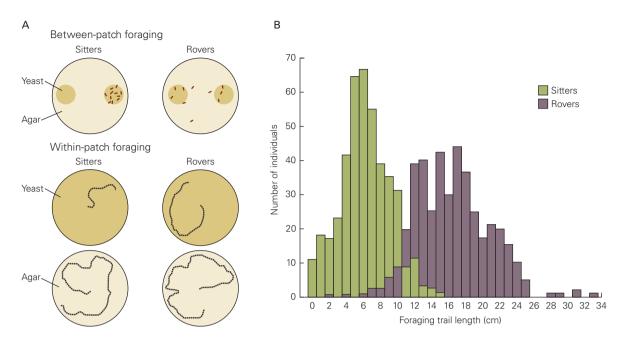

Figure 3–12 Foraging behavior of *Drosophila melanogaster* **larvae**. The larvae feast on patches of yeast. Rover-type larvae move from patch to patch, whereas sitter-type larvae stay put on a single patch for a long time. When foraging within a single patch, rover larvae move about more than sitter larvae. On agar

alone, rover and sitter larvae move about equally. This difference in foraging behavior maps to a single protein kinase gene, for, that varies in activity in different fly larvae. (Reproduced, with permission, from Sokolowski 2001.)

forms: There is balanced selection for both behaviors. Crowded environments favor the rover larva, which is more effective at moving to new, unexploited food sources in advance of competitors, whereas sparse environments favor the sitter larva, which exploits the current source more thoroughly.

The *for* gene also affects honeybee behavior. Honeybees exhibit different behaviors at different stages of their life; in general, young bees are nurses, while older bees become foragers that leave the hive. The *for* gene is expressed at high levels in the brains of active foraging honeybees, and at low levels in the younger and more stationary nurse bees. Activation of cGMP signaling in young bees can cause them to enter the forager stage prematurely. Presumably, this change is normally programmed by an environmental stimulus or the bee's advancing age. Thus the same gene controls variation in a behavior in two different insects, the fruit fly and the bee. However, in the fruit fly the variation is expressed in different individuals, whereas in the honeybee it is expressed in one individual at different ages. The difference illustrates how an important regulatory gene can be recruited to different behavioral strategies in different species.

The Social Behaviors of Several Species Are Regulated by Neuropeptide Receptors

Many aspects of behavior are associated with an animal's social interactions with other animals. Social behaviors are highly variable between species, yet have a large innate component within a species that is controlled genetically. A simple form of social behavior has been analyzed in the roundworm *C. elegans*. These animals live in soil and eat bacteria. Different wild-type strains exhibit profound differences in feeding behavior. Some strains are solitary, dispersing across a lawn of bacterial food and failing to interact with each other. Other strains have a social feeding pattern, joining large feeding groups of dozens or hundreds of animals (Figure 3–13). The difference between these strains is genetic, as both feeding patterns are stably inherited.

The difference between social and solitary worms is caused by a single amino acid substitution in a single gene, a member of a large family of genes involved in signaling between neurons. This gene, *npr-1*, encodes a neuropeptide receptor. Neuropeptides have long been appreciated for their roles in coordinating behaviors across networks of neurons. For example,

a neuropeptide hormone of the marine snail *Aplysia* stimulates a complex set of movements and behavior patterns associated with a single behavior, egg laying. Mammalian neuropeptides have been implicated in feeding behavior, sleep, pain, and many other behaviors and physiological processes. The existence of a mutation in the neuropeptide receptor that alters social behavior suggests that this kind of signaling molecule is important both for generating the behavior and for generating the variation between individuals.

Neuropeptide receptors have also been implicated in the regulation of mammalian social behavior. The neuropeptides oxytocin and vasopressin stimulate mammalian affiliative behaviors such as pair bonding and parental bonding with offspring. Oxytocin is required in mice for social recognition, the ability to identify a familiar individual. Oxytocin and vasopressin have been studied in depth in prairie voles, rodents that form lasting pairs to raise their young. Oxytocin released in the brain of female prairie voles during mating stimulates pair-bond formation. Likewise, vasopressin released in the brain of male prairie voles during mating stimulates pair-bond formation and paternal behavior.

The extent of pair-bonding varies substantially between mammalian species. Male prairie voles form pair-bonds with females and help them raise their off-spring, but the closely related male montane voles breed widely and do not engage in paternal behavior. The difference between the behaviors of males in these species correlates with differences in the expression of the V1a class of vasopressin receptors in the brain. In prairie voles V1a vasopressin receptors are expressed at high levels in a specific brain region, the ventral pallidum (Figure 3–14). In montane voles the levels are much lower in this region, although high in other brain regions.

The importance of oxytocin and vasopressin and their receptors has been confirmed and extended by reverse genetic studies in mice, which are genetically easier to manipulate than voles. For example, introducing the V1a vasopressin receptor gene from prairie voles into male mice, which behave more like montane voles, increases the expression of the V1a vasopressin receptor in the ventral pallidum and increases the affiliative behavior of the male mice toward females. Thus differences between species in the pattern of expression of the vasopressin receptor can contribute to differences in social behaviors.

The analysis of vasopressin receptors in different rodents provides insight into the mechanisms by which genes and behaviors can change during evolution. Genetic changes in evolution alter the pattern of expression of the V1a vasopressin receptor in the ventral forebrain. These changes in turn alter the activity of a neural circuit, so that the function of the ventral forebrain is linked to the function of the vasopressin-secreting neurons that are activated by mating. As a result, social behaviors are altered.

The importance of oxytocin and vasopressin in human social behavior is not known, but the central role of pair-bonding and pup rearing in mammalian species suggests that these molecules might play a role in our species as well.

Genetic Studies of Human Behavior and Its Abnormalities

Human genetics is studied by observing traits that vary between individuals, analyzing pedigrees to trace the transmission of genetic traits across generations, and identifying functional variants using molecular

Figure 3–13 Feeding behavior of the roundworm *Caenorhabditis elegans* depends on the level of activity of a neuropeptide receptor gene. In one strain individual worms graze in isolation (left), whereas in another strain individuals mass together to feed. The difference is explained by a single amino acid substitution in the neuropeptide receptor gene. (Reproduced, with permission, from Mario de Bono and Cell Press.)

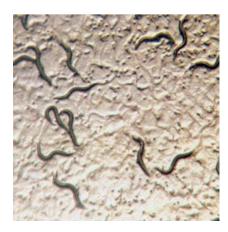

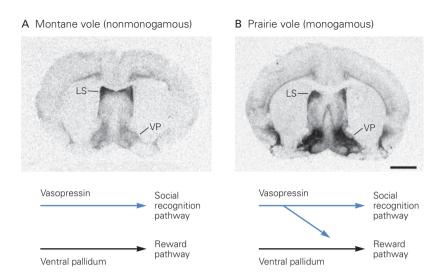

Figure 3–14 Distribution of vasopressin (V1a) receptor binding in the ventral pallidum of montane voles (nonmonogamous) and prairie voles (monogamous). (Adapted, with permission, from Young et al. 2001.)

- A. V1a receptor expression is high in the lateral septum (LS) but low in the ventral pallidum (VP) in the nonmonogamous montane vole.
- **B.** Expression is high in the ventral pallidum of the monogamous prairie vole. Expression of the receptor in the ventral pallidum allows vasopressin to link the social recognition pathway to the reward pathway.

biology. Human genetics is more challenging than experimental genetics because one cannot do inbreeding or crossbreeding experiments in people as one can in worms, flies, or mice.

Nonetheless, careful pedigree tracing has identified a variety of mutations that affect the human brain and behavior, including mutations that lead to neurodegenerative diseases, neurological disorders, and developmental disorders. In some cases mutations in a single gene have large effects on a neurological or behavioral trait. However, most neurological or psychiatric diseases are believed to reflect interactions between multiple genes and the environment, and our ability to tease apart these influences is still limited.

The first gene discovered to be important for a neurological disease in humans was the gene responsible for phenylketonuria (PKU), described by Asbørn Følling in Norway in 1934. This rare disease affects 1 in 15,000 children and results in severe impairment of cognitive function. Children with this disease have two abnormal copies of the gene that codes for phenylalanine hydroxylase, the enzyme that converts the amino acid phenylalanine to tyrosine. The mutation is recessive; heterozygous carrier individuals have no symptoms. Children who lack normal function in both copies of the gene accumulate high blood concentrations of phenylalanine from dietary proteins, which in turn leads to the production of toxic metabolites that interfere with neuronal function. The specific biochemical processes by which phenylalanine adversely affects the brain are still not understood.

The PKU phenotype (mental retardation) results from the interaction of the genotype (the homozygous *pku* mutation) and the environment (the diet). The

treatment for PKU is thus simple and effective: Mental retardation can be prevented by a low-protein diet. The molecular and genetic analysis of gene function in PKU has led to dramatic improvements in the life of PKU patients. Since the early 1960s the United States has instated mandatory testing for PKU in newborns. By identifying children with the genetic disorder and modifying their diet before the disease appears many aspects of the disorder can be prevented.

Later chapters of this book describe many examples of single-gene traits that, like PKU, have led to insights into brain function and dysfunction. Certain themes have emerged from these studies. A number of rare neurodegenerative disorders such as Huntington disease and spinocerebellar ataxia result from the pathological, dominant expansion of glutamate residues within proteins. The discovery of these polyglutamine repeat disorders highlighted the danger to the brain of unfolded and aggregated proteins. The discovery that epileptic seizures can be caused by a variety of mutations in ion channels led to the realization that these disorders are primarily disorders of neuronal excitability.

The single-gene disorders mentioned earlier are rare compared to the total burden of neurodegenerative and psychiatric disease. One might wonder why we study rare single-gene variants if they represent a tiny fraction of the total disease burden. The reason is that rare, relatively simple disorders can provide insight into the biological processes affected in more common, complex forms of the disease. For example, among the prominent successes of human genetics has been the discovery of rare genetic variants that lead to early-onset Alzheimer disease or Parkinson disease.

Individuals with these severe rare variants represent a tiny subset of all individuals with Alzheimer disease or Parkinson disease, but the rare variants uncovered cellular processes that are also disrupted in the larger patient pool, pointing the way to general therapeutic avenues.

In the remainder of this chapter we discuss the genetics of autism and schizophrenia, two psychiatric disorders that manifest themselves in child-hood or adolescence, respectively. Compared to the polyglutamine repeat diseases or ion channel-related seizure disorders, the biological causes of autism and schizophrenia are still largely unknown. Nonetheless, in some cases we can begin to see how certain genes, and the associated biological processes, affect complex brain functions such as language, learning, and emotion.

Neurological Disorders in Humans Suggest That Distinct Genes Affect Different Brain Functions

Autism is a common, devastating developmental disorder characterized by deficiencies in language acquisition, difficulties in social interactions, and stereotyped interests. About 1 in 200 children are diagnosed with autism (the exact frequency varies with diagnostic criteria), with about three times as many boys affected as girls. The clinical symptoms of autism typically emerge in the first 3 years of life and often include a regression phase in which children lose the language skills they mastered when younger.

There is considerable variability between autistic individuals. Children affected with autism have a higher frequency of seizures and cognitive problems than the general population, and some are severely disabled. However, many autistic individuals have normal or above-normal intelligence, and can, with appropriate care, goes on to lead highly successful lives.

Autism has a very strong heritable component (see Figure 3–1A), which should increase the chances of identifying the underlying genes. Autism is also a disorder of broader significance because it provides insight into behaviors that are unique to humans: language, complex intelligence, and interpersonal interactions. The fact that autistic defects in social communication can coexist with normal intelligence in other domains suggests that the brain is modular, with distinct cognitive functions that can vary independently.

The idea that distinct genes affect different cognitive domains is supported by the contrasting effects of a rare genetic syndrome called Williams syndrome. Children with Williams syndrome acquire language late, but they ultimately overcome their early deficits to develop strong language skills and normal social

behavior. Indeed, these children exhibit extreme sociability; for example, they lack the shyness children typically have in the presence of strangers. However, Williams children are profoundly defective in spatial processing, and they score as poorly as, or even worse than, autistic children on IQ tests. The different patterns of impairments in autism and Williams syndrome suggest that language and social skills can be separated from some other brain functions. Brain areas concerned with language are impaired in autistic children but active or accented in Williams syndrome children. By contrast, general and spatial intelligence is more impaired in Williams syndrome than in many autistic children.

Williams syndrome is genetically simple; it is caused by a heterozygous deletion of chromosome region 7q11.23. The simplest interpretation of this defect is that the level of expression of one or more genes within this interval is reduced because there is only one copy instead of two of each gene in the region. The precise genes in this region that affect sociability and spatial processing are not yet known, but they are of great interest because of their potential to provide insight into the genetic regulation of human behaviors.

Another rare syndrome has shed light on genetic requirements for human language. A study of a human family with defects in speech articulation, as well as grammatical and linguistic impairment, led to the identification of a specific mutation in the transcriptional regulator *FOXP2*. This gene is not uniquely human—it is present in all mammals and birds—but several changes in the gene have appeared since the divergence of humans and other primates. A human-specific pattern of development of the brain, larynx, or mouth under the control of *FOXP2* might be one of the genetic adaptations that made human speech possible.

Autism-Related Disorders Exemplify the Complex Genetic Basis of Behavioral Traits

Autism is a common disorder, yet there is no single genetic location for autism as there is for the much rarer Williams syndrome. At least part of the explanation for this difference is that autism is not really one disorder caused by a single kind of genetic lesion, but rather a cluster of related disorders caused by a variety of different genetic changes. The recognition of this genetic complexity is providing inroads into autism and related syndromes that affect social communication and language.

The symptoms of classical autism partly overlap with those of a number of genetic disorders whose genetic basis is understood. For example like autism, fragile X syndrome affects mostly boys, and patients have poor social cognition, high social anxiety, and repetitive behavior. However, fragile X syndrome is associated with broader cognitive defects, along with certain physical characteristics, like an elongated face and protruding ears. Fragile X syndrome has been genetically associated with a mutation that reduces expression of a single gene on the X chromosome. This gene regulates the translation of mRNAs into proteins in neurons, a process that is regulated during synaptic plasticity and learning. The male preponderance of fragile X syndrome is explained because males have only a single X chromosome, and therefore lose all expression of the relevant gene when it is mutated. Since females have two X chromosomes, they can be carriers of the disease without being strongly affected.

Another autism-like syndrome whose genetic basis is understood is Rett syndrome, which we consider in detail in Chapter 64. Rett syndrome is an X-linked, progressive neurodevelopmental disorder and one of the most common causes of mental retardation in females. The disease is confined to females because Rett syndrome is lethal in the developing male embryo, which has a single X chromosome. Affected girls seem to develop normally until they are 6 to 18 months of age, when they fail to acquire speech and purposeful hand use is replaced by compulsive, uncontrolled handwringing.

Huda Zoghbi and her colleagues found that the major cause of this disease is a mutation in the methyl CpG binding protein 2 (*MeCP2*) gene. Methylation of specific CpG sequences in DNA alters expression of nearby genes, and it is thought that *MeCP2* binds methylated DNA as part of a process that regulates mRNA transcription. This discovery shows that acquisition of complex developmental properties such as language is associated with specific patterns of gene expression, most likely in the brain. Current research on Rett syndrome focuses on identifying the affected brain regions and the inappropriately transcribed genes in these children.

Psychiatric Disorders and the Challenge of Understanding Multigenic Traits

The observation that common diseases such as autism are less well understood than rare diseases such as Rett syndrome applies broadly to psychiatric disorders. Schizophrenia affects about 1% of all young adults, causing a pattern of thought disorders and emotional withdrawal that profoundly impairs life. It is strongly heritable (see Figure 3–1B), but its genetic basis is

poorly understood. Despite evidence of heritability, and despite progress in research on individual diseases using experimental animal models, it has been difficult to identify the genes associated with many common human psychiatric diseases like chronic depression and anxiety disorders, which affect a substantial fraction of people. In this final section of the chapter we survey the approaches that are being developed to address these shortfalls.

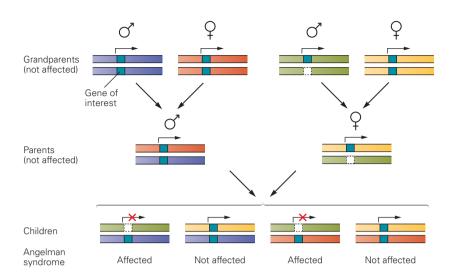

Complex Inheritance and Genetic Imprinting in Human Genetics

Understanding Mendelian inheritance is not always sufficient for understanding human genetic disorders. For example, studies of human developmental disorders have shown important effects of an unusual form of gene regulation called *parental imprinting*. Although humans have two copies of all autosomes, they sometimes express mRNA from only one of the two copies of a gene, either the copy from the mother or the copy from the father. Angelman syndrome and Prader-Willi syndrome are examples of genetic diseases with a complex heritability caused by parental imprinting. To understand these diseases, one must not only know the DNA lesion associated with the disease but also understand whether the DNA lesion was inherited from the father or the mother (Figure 3–15).

Angelman syndrome is an inherited disorder that can include severe mental retardation, epilepsy, absence of speech, hyperactivity, and inappropriate laughter. The syndrome results from deletion of multiple genes on one copy of the chromosome region 15q11-q13. In this region some genes are expressed only from the maternally derived chromosome, and a different set of genes are expressed only from the paternally derived chromosome. The genes implicated in Angelman syndrome are expressed only from the maternally derived chromosome. Therefore, if a child receives a normal chromosome from her mother and an abnormal chromosome with a deletion from her father, she will not have Angelman syndrome. However, if she receives a normal chromosome from her father and an abnormal chromosome from her mother, she will have Angelman syndrome.

For Angelman syndrome the most important gene in this region appears to be the gene that encodes UBE3A, a ubiquitin-protein ligase that is expressed only from the maternally derived chromosome. Ubiquitin ligases stimulate the degradation and turnover of other proteins. The important targets of UBE3A are thought to regulate general brain plasticity, perhaps by regulating the activity of neurotransmitter receptors.

Figure 3–15 Expression of an imprinted gene. Imprinted genes are expressed from only one of two chromosomes, either the chromosome derived from the father or the one derived from the mother. In this example the gene responsible for Angelman syndrome is expressed only from the maternally derived chromosome. If this chromosome has a deletion (dashed region), the child has symptoms of the disease.

A different neurodevelopmental behavioral disorder, Prader-Willi syndrome, is also caused by a deletion of multiple genes on chromosome 15q11-q13, but the genes implicated in Prader-Willi syndrome are expressed only from the paternally derived chromosome. Therefore, Prader-Willi syndrome results from the reciprocal of the pattern of inheritance in Angelman syndrome: A child must receive the abnormal chromosome from his father to develop Prader-Willi syndrome. Prader-Willi syndrome is associated with obesity, and psychiatric symptoms include obsessive-compulsive behavior, bipolar disorder, and pervasive developmental disorders.

Parental imprinting is an example of the complexity that can confound expectations in human gene mapping. Recent studies in mice by Catherine Dulac's group suggest that parental imprinting is more common in the brain than it is in other tissues in the body. If this observation holds true in humans, it could help explain why mapping human behavioral traits is difficult.

Multigenic Traits: Many Rare Diseases or a Few Common Variants?

Genetic mapping methods that follow linkage across generations are highly effective in identifying singlegene traits (Box 3–4). However, most common genetic disorders in humans cannot be followed through pedigrees as single-gene traits, and they are suspected or known to involve multiple genes as well as genetic interactions with the environment. Schizophrenia, autism, and depression fall into this category, as do diabetes, coronary artery disease, and asthma.

In contrast to single-locus Mendelian traits, multigenic traits do not have a simple recognizable pattern of inheritance (autosomal dominant, recessive, or X-linked), and thus the relative contributions of several genes to one trait are difficult to analyze. Nevertheless, determining which genes contribute to complex human traits has profound implications for the care and treatment of human disease and therefore is an area of intense study.

To understand complex psychiatric disorders it will be important to distinguish between various models of transmission. According to one (monogenic) model, many genes in the population can contribute to a disorder, but each gene mutation is individually rare and has a strong effect. Taking the examples described earlier in the chapter, it is known that *MeCP2* mutations (Rett syndrome) and fragile X mutations each account for 1–2% of children with autism-related disorders. In a rare monogenic model there might be 100 other mutations, each individually rare, that can result in autism.

A second (polygenic) model assumes that a small number of relatively common mutations, each of which has only a small effect on risk, interact together to cause a disorder. The latter model is sometimes called the "common variant – common disease" hypothesis. Common human variants are known to increase the risk of some common diseases such as macular degeneration, which leads to adult-onset blindness. Thus, there are well-understood examples of both the monogenic and polygenic models in human genetics. An important question is the extent to which each model contributes to the burden of psychiatric diseases.

Box 3-4 Genetic Polymorphisms and Linkage Mapping

The most common strategy for finding genes that affect humans has been *linkage analysis*, which takes advantage of the fact that two random individuals differ in their DNA sequences at many positions in the genome. The sequence variants, which are usually functionally neutral, are called *DNA polymorphisms*, and the most restricted changes are called *single nucleotide polymorphisms*.

DNA polymorphisms are tracked by a variety of methods, usually by amplifying specific regions from an individual's DNA and examining the sequence of those regions. In linkage mapping the segregation of many different DNA polymorphisms is correlated with the segregation of the genetic trait of interest in the same families. Coinheritance of a DNA marker and mutant phenotype (or disease state) suggests that the marker and the mutant gene lie close together on the chromosome (Figure 3–16).

A DNA marker that is linked to a mutant gene is almost always coinherited with the mutant gene, whereas DNA marker and mutant gene that are not linked are coinherited only by chance. The chance that any two unlinked loci—for example, loci from different chromosomes—will be inherited together is 1/2, and the chance that they will be coinherited in n siblings is $(1/2)^n$. Thus, if two loci are coinherited in all eight affected siblings from a single family, the odds against this being a random event would be $(1/2)^8 = 256:1$.

A statistically rigorous linkage value based on family trait mapping and specific models of inheritance is called the *lod* (logarithm of odds) score. For practical purposes a lod score equal to or greater than 3 indicates

that a DNA marker is significantly linked to a genetic trait. The discovery of a high lod score is the first step in finding the right gene.

Typically, the region is narrowed down by seeking many additional polymorphic DNA markers that are on chromosome regions near the first linked DNA marker. A careful analysis is then conducted to ask which polymorphic DNA markers are coinherited with the genetic trait most frequently. Genes involved in many human neurological diseases have been pinpointed using this approach.

Despite its power, classical linkage analysis failed to reveal genes for schizophrenia and bipolar disorder, and this failure inspired the development of alternative strategies for mapping human genetic traits. One strategy continues to rely on tracking transmission through families but uses models that are less rigid than those of classical linkage analysis. This method does not make assumptions about whether a mutation is dominant or recessive but assumes only that linked DNA will tend to be coinherited in two affected siblings. Another strategy uses quantitative models to assist the identification of genes that contribute some genetic variance to a multigenic trait (quantitative trait loci).

Finally, the completion of the human genome sequence is being followed by identification of many DNA polymorphisms in the human genome and resequencing of many regions of the genome from hundreds of individuals. A fuller understanding of the genetic variance in our human heritage may provide clues about how to identify the DNA polymorphisms that lead to psychiatric illness.

In both the "rare monogenic" model and the "common variant – common disease" model, it is challenging to identify the effects of individual mutations. Therefore, current psychiatric genetic studies usually involve international consortia cooperating in the diagnosis of very large clinical groups of patients. These studies can be analyzed using both monogenic and polygenic models of inheritance, and an increasingly sophisticated array of genotyping methods to assess correlations between regions of the genome and traits of interest (Box 3–4). Promising results have emerged from a variety of studies. Verification of these results

will require independent replication of results and very large numbers of patients. With that caveat, some of the first fruits of these studies are described below.

A successful single-gene mapping study of a large Scottish family with a high rate of schizophrenia led to the identification of the risk gene *Disc1* (for Disrupted in Schizophrenia). In mice *Disc1* has effects on neuronal development, neuronal signaling, and the incorporation of newborn neurons into neural circuits. In humans a *Disc1* mutation greatly increases the risk of schizophrenia, but it is mutated only in a small fraction of schizophrenic patients. Other candidate genes for

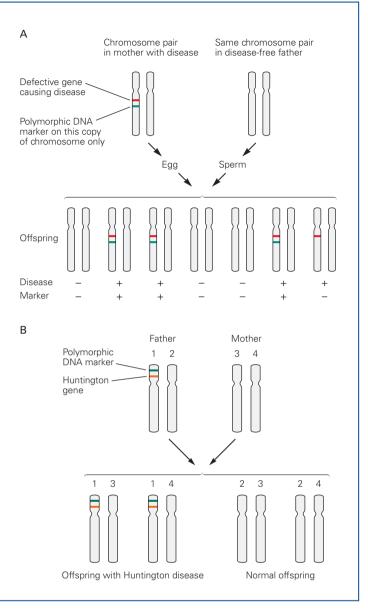

Figure 3-16 Methods for mapping human genes.

A. Genetic linkage analysis detects the coinheritance of a mutated gene responsible for a human disease and a nearby polymorphic DNA marker. In this example the gene responsible for the disease is inherited in four offspring, three of which coinherit the marker. Thus the gene responsible for the disease is located close to the polymorphic DNA marker on this chromosome. The presence of the polymorphic marker is scored by direct sequencing of the human DNAs or by physical techniques that detect nucleotide mismatches between a reference sequence and the sequence being tested.

B. Inheritance of the gene responsible for Huntington disease can be traced by following the inheritance of a particular polymorphic DNA marker on chromosome 4.

schizophrenia have been identified from the alternative approach of looking for statistical associations between the disorder and specific loci in the genome in a sample of thousands of schizophrenic patients from different families. One risk gene identified in this way is *neuregulin*, a developmental signaling gene that affects cell migration and synapse formation. Together the studies of *Disc1* and *neuregulin* begin to suggest that a developmental defect in the brain can underlie schizophrenia.

Similar large-scale studies of thousands of autistic children and their families have led to the repeated identification of mutations in certain autism risk genes.

Several mutations in autistic patients affect transmembrane signaling proteins called neurexins and neuroligins, which affect the strength of synapses. These results and other genetic results suggest that subtle alterations in synaptic transmission play a role in autism. Sophisticated genetic analysis suggests that an increased risk for autism exists at many locations in the genome (Figure 3–17). Some of these loci may be rare monogenic high-risk variants and others may be more common, low-risk variants.

One remarkable discovery made by Michael Wigler's group while trying to understand the genetic basis of

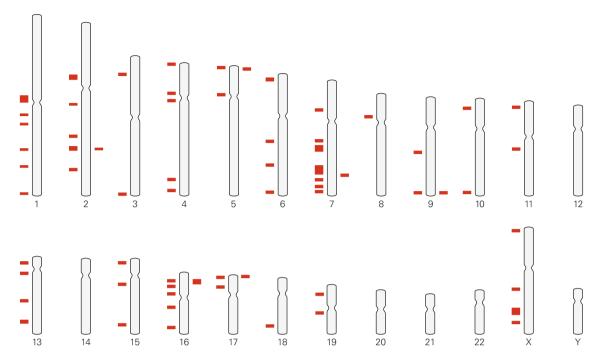

Figure 3–17 Candidate loci that contribute to autism spectrum disorders. The loci were identified in several published genome screens. Many different loci may increase the risk of autism. The most consistent signal reported in multiple studies

is on the long arm of chromosome 7, but there is also overlap of different studies on chromosomes 2 and 16. No one locus appears in all studies. (Reproduced, with permission, from Folstein et al. 2001.)

autism is that a fraction of the mutations associated with autism are not actually inherited from either parent. They are new mutations in the autistic child that arose in the sperm or the oocyte prior to fertilization. Identical monozygotic twins that separate after fertilization will both have the trait, the classical definition of heritability. Moreover, once the mutation arises, the affected child has a trait that can be passed on to his or her children, so it is indeed a heritable trait. However, classical genetic linkage studies rely on the assumption that virtually all disease-causing mutations are preexisting mutations inherited across many generations, and the finding of new mutations in autism violate that expectation. Human biology is a constant source of surprises.

New tools are being developed to help address the complexities of multigenic traits. For example, brain imaging techniques are being used to pinpoint anatomical loci underlying clinical syndromes that might be caused by specific mutations. At this writing, it will soon be possible to sequence the complete genomes of individual psychiatric patients to discover genetic variants. Even when these sequences are available, however, we will still need sophisticated approaches to ask which of the many variations that distinguish one human being from every other human being represent the risk factors for disease.

An Overall View

Genes affect many aspects of behavior. There are remarkable similarities in personality traits and psychiatric illnesses in human twins, even those raised separately; domestic and laboratory animals can be bred for particular, stable behavioral traits; a few specific genes are associated with human behaviors.

In recent years we have seen great success in identifying the genes associated with neurological diseases such as Alzheimer disease, Parkinson disease, Huntington disease, and spinocerebellar ataxias, as well as those associated with developmental disorders such as Rett syndrome and Angelman syndrome. What we have learned about the genetic basis of these diseases may help us fashion approaches to researching the more difficult psychiatric diseases such as schizophrenia, depression, and autism.

Human behavioral traits are multigenic in origin. Although alterations in a single gene account for individual differences in social behavior in nematodes and activity levels in *Drosophila*, only rarely will genetic alteration at a single gene fully explain a psychiatric disease or a behavior in humans. More frequently, several different genes will each act independently

to affect a trait, or have effects only in combination with each other. Model organisms such as the fly, the worm, and the mouse are important for genetics because they are experimentally tractable. By studying genes in these simple animals, where the genome and environment can be rigorously controlled, it is possible to identify the conserved biological pathways that mediate behavior in humans. Several successes have emerged from this approach. The *per* gene in the fruit fly led to an understanding of human advanced sleep phase syndrome, and the gene for narcolepsy in dogs has led to an understanding of the underlying biology of sleep in humans (see Chapter 51).

There is still much to learn about the ways that genes affect the brain. Biologists are becoming more skilled at delineating the role of individual genes within particular neurons and circuits. There are important insights to be gained about the genetics of psychiatric disease and the genetic influences on normal psychological, physiological, and cognitive traits. Yet it is the interplay of genetics, environment, chance, and individual choice that ultimately determines the behavioral differences between individuals. The challenge of genetics is to understand the undeniable effects of genes, while acknowledging that many factors influence human mental processes and behavior.

Glossary¹

Allele. Humans carry two sets of chromosomes, one from each parent. Equivalent genes in the two sets might be different, for example, because of single nucleotide polymorphisms. An allele is one of the two (or more) forms of a particular gene.

Centromere. Chromosomes contain a compact region known as a centromere, where sister chromatids (the two exact copies of each chromosome that are formed after replication) are joined.

Cloning. The process of generating sufficient copies of a particular piece of DNA to allow it to be sequenced or studied in some other way.

Complementary DNA (cDNA). A DNA sequence made from a messenger RNA molecule, using an enzyme called *reverse transcriptase*. cDNAs can be used experimentally to determine the sequence of messenger RNAs after their introns (nonprotein-coding sections) have been spliced out.

Conservation of genes. Genes that are present in two distinct species are said to be conserved, and the two

genes from the different species are called *orthologous genes*. Conservation can be detected by measuring the similarity of the two sequences at the base (RNA or DNA) or amino acid (protein) level. The more similarities there are, the more highly conserved the two sequences.

Copy number variation (CNV). A deletion or duplication of a limited genetic region that results in an individual having more or fewer than the usual two copies of some genes. Copy number variations are observed in some neurological and psychiatric disorders.

Euchromatin. The gene-rich regions of a genome (see also heterochromatin).

Eukaryote. An organism with cells that have a complex internal structure, including a nucleus. Animals, plants, and fungi are all eukaryotes.

Genome. The complete DNA sequence of an organism.

Genotype. The set of genes that an individual carries; usually refers to the particular pair of alleles (alternative forms of a gene) that a person has at a given region of the genome.

Haplotype. A particular combination of alleles (alternative forms of genes) or sequence variations that are closely linked—that is, are likely to be inherited together—on the same chromosome.

Heterochromatin. Compact, gene-poor regions of a genome, which are enriched in simple sequence repeats. Introns and exons. Genes are transcribed as continuous sequences, but only some segments of the resulting messenger RNA molecules contain information that encodes a protein product. These segments are called exons. The regions between exons are known as introns and are spliced from the RNA before the product is made.

Long and short arms. The regions on either side of the centromere are known as arms. As the centromere is not in the center of the chromosome, one arm is longer than the other.

Messenger RNA (mRNA). Proteins are not synthesized directly from genomic DNA. Instead, an RNA template (a precursor mRNA) is constructed from the sequence of the gene. This RNA is then processed in various ways, including splicing. Spliced RNAs destined to become templates for protein synthesis are known as mRNAs.

Mutation. An alteration in a genome compared to some reference state. Mutations do not always have harmful effects.

Phenotype. The observable properties and physical characteristics of an organism.

Polymorphism. A region of the genome that varies between individual members of a population. To be called a polymorphism, a variant should be present in a significant number of people in the population.

¹From P. Bork and R. Copley. 2001. Genome speak. *Nature* 409:815.

Prokaryote. A single-celled organism with a simple internal structure and no nucleus. Bacteria and Archaebacteria are prokaryotes.

Proteome. The complete set of proteins encoded by the genome.

Recombination. The process by which DNA is exchanged between pairs of equivalent chromosomes during egg and sperm formation. Recombination has the effect of making the chromosomes of the offspring distinct from those of the parents.

Restriction endonuclease. An enzyme that cleaves DNA at a particular short sequence. Different types of restriction endonuclease cleave at different sequences.

RNA interference (RNAi). A method for reducing the function of a specific gene by introducing into a cell small RNAs with complementarity to the targeted mRNA. Pairing of the mRNA with the small RNA leads to destruction of the endogenous mRNA.

Single nucleotide polymorphism (SNP). A polymorphism caused by the change of a single nucleotide. SNPs are often used in genetic mapping studies.

Splicing. The process that removes introns (noncoding portions) from transcribed RNAs. Exons (protein-coding portions) can also be removed. Depending on which exons are removed, different proteins can be made from the same initial RNA or gene. Different proteins created in this way are *splice variants* or *alternatively spliced*.

Transcription. The process of copying a gene into RNA. This is the first step in turning a gene into a protein, although not all transcripts lead to proteins.

Transcriptome. The complete set of RNAs transcribed from a genome.

Translation. The process of using a messenger RNA sequence to build a protein. The messenger RNA serves as a template on which transfer RNA molecules, carrying amino acids, are lined up. The amino acids are then linked together to form a protein chain.

Part II

Preceding Page Retinal ganglion cells arrayed across the retina are illuminated by a transgenic marker (junctional adhesion molecule B [JAM-B]). Whereas the axons of all ganglion cells converge at the back of the eye and exit the retina as the optic nerve en route to the brain, the dendrites of this particular set of neurons also share the same orientation, branching downward from the cell bodies. Their common form reflects a common function: detection of upward motion in the visual field. (Reproduced, with permission, from In-Jung Kim and Joshua Sanes.)

\mathbf{II}

Cell and Molecular Biology of the Neuron

In all BIOLOGICAL SYSTEMS, from the most primitive to the most advanced, the basic building block is the cell. Cells are often organized into functional modules that are repeated in complex biological systems. The vertebrate brain is the most complex example of a modular system. Complex biological systems have another structural feature: They are architectonic—that is, their anatomy, fine structure, and biochemistry all reflect a specific physiological function. Thus, the construction of the brain and the cell biology, biophysics, and biochemistry of its component neurons reflect its fundamental function, which is to mediate behavior.

The great diversity of nerve cells—the fundamental units from which the modules of the nervous systems are assembled—is derived from one basic cell plan. Three features of this plan give nerve cells the unique ability to communicate with one another precisely and rapidly over long distances. First, the neuron is polarized, possessing receptive dendrites on one end and communicating axons with synaptic terminals at the other. This polarization of functional properties is commonly used to restrict the flow of impulses to one direction. Second, the neuron is electrically and chemically excitable. Its cell membrane contains specialized proteins—ion channels and receptors—that permit the influx and efflux of specific inorganic ions, thus creating electrical currents that alter the voltage across the membrane. Third, the neuron contains proteins and organelles that endow it with specialized secretory properties that allow it to release neurotransmitters at synapses.

In this part of the book, we shall be concerned with the properties of the neuron that give it the ability to generate electrical signals in the form of synaptic and action potentials (see Chapter 4). The initiation of a signal depends on ion channels in the cell membrane that open in response to changes in membrane voltage and to neurotransmitters released by other nerve cells. In Chapter 5, we consider general properties of ion channels. Neurons use three major classes of channels for signaling: (1) resting channels generate the resting potential and underlie the passive properties of neurons that determine the time course of synaptic potentials, their spread along dendrites, and the threshold for firing an action potential, as discussed in Chapter 6; (2) voltage-gated channels are responsible for

the active currents that generate the action potential, which is discussed in Chapter 7; and (3) ligand-gated channels open in response to neurotransmitters to generate synaptic potentials. In this section, we focus mainly on resting and voltage-gated channels. In the next section, we consider in more detail ligand-gated channels.

An Overall View

TEURONS AND GLIA—the cells from which the nervous system is assembled—share many characteristics with cells in general. However, neurons are specially endowed with the ability to communicate precisely and rapidly with other cells at distant sites in the body. Two features give neurons this ability.

First, they have a high degree of morphological and functional asymmetry: Neurons have receptive dendrites at one end and a transmitting axon at the other. This arrangement is the structural basis for unidirectional neuronal signaling.

Second, neurons are both electrically and chemically excitable. The cell membrane of neurons contains specialized proteins—ion channels and receptors—that facilitate the flow of specific inorganic ions, thereby redistributing charge and creating electrical currents that alter the voltage across the membrane. These changes in charge can produce a wave of depolarization in the form of action potentials along the axon, the usual way a signal travels within the neuron. Glia are less excitable, but their membranes contain transporter proteins that facilitate the uptake of ions as well as proteins that remove neurotransmitter molecules from the extracellular space, thus regulating neuronal function.

There are about 100 distinct types of neurons. This cytological diversity is also apparent at the molecular level. Although neurons all inherit the same complement of genes, each expresses a restricted set and thus produces only certain molecules—enzymes, structural proteins, membrane constituents, and secretory products—and not others. In large part this expression depends on the cell's developmental history. In essence each cell *is* the set of molecules that it makes.

Neurons and Glia Share Many Structural and Molecular Characteristics

Neurons and glia develop from common neuroepithelial cells of the embryonic nervous system and thus

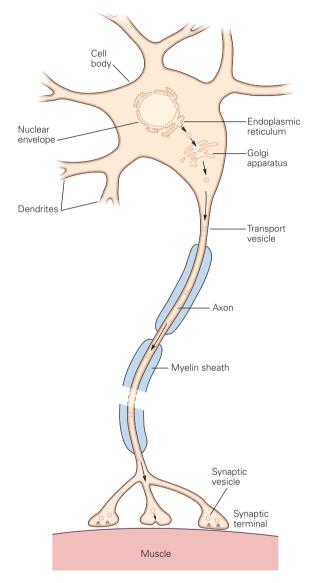

Figure 4–1 The structure of a neuron. The cell body and nucleus of a spinal motor neuron are surrounded by a double-layered membrane, the nuclear envelope, which is continuous with the endoplasmic reticulum. The space between the two membrane layers that constitutes the nuclear envelope is continuous with the lumen of the endoplasmic reticulum. Dendrites emerge from the basal aspect of the neuron, the axon from the apical aspect. (Adapted, with permission, from Williams et al. 1989.)

share many structural and molecular characteristics (Figure 4–1). The boundaries of these cells are defined by the cell membrane or *plasmalemma*, which has the asymmetric bilayer structure of all biological membranes and provides a hydrophobic barrier impermeable to most water-soluble substances. Cytoplasm has two main components: cytosol and membranous organelles.

Cytosol is the aqueous phase of cytoplasm. In this phase only a few proteins are actually free in solution. With the exception of some enzymes that catalyze metabolic reactions, most proteins are organized into functional complexes. A recent subdiscipline called proteomics has determined that these complexes can consist of many distinct proteins, none of which are covalently linked to another. For example, the cytoplasmic tail of the N-methyl-D-aspartate (NMDA)-type glutamate receptor, a membrane-associated protein that mediates excitatory synaptic transmission in the central nervous system, is anchored in a large complex of more than 100 scaffold proteins and protein-modifying enzymes. (Many cytosolic proteins involved in second-messenger signaling, discussed in later chapters, are embedded in the cytoskeletal matrix immediately underneath the plasmalemma.) Ribosomes, the organelle on which messenger RNA (mRNA) molecules are translated, are made up of several protein subunits. Proteasomes, large multienzyme organelles that degrade ubiquitinated proteins (a process described later in this chapter), are also present throughout the cytosol of neurons and glia.

Membranous organelles, the second main component of cytoplasm, include mitochondria and peroxisomes as well as a complex system of tubules, vesicles, and cisternae called the *vacuolar apparatus*. Mitochondria and peroxisomes process molecular oxygen. Mitochondria generate adenosine triphosphate (ATP), the major molecule by which cellular energy is transferred or spent, whereas peroxisomes prevent accumulation of the strong oxidizing agent hydrogen peroxide. Thought to be derived from symbiotic organisms that invaded eukaryotic cells early in evolution, these two organelles are not functionally continuous with the vacuolar apparatus.

The vacuolar apparatus includes the rough endoplasmic reticulum, the smooth endoplasmic reticulum, the Golgi complex, secretory vesicles, endosomes, lysosomes, and a multiplicity of transport vesicles that interconnect these various compartments (Figure 4–2). Their lumen corresponds topologically to the outside of the cell; consequently, the inner leaflet of their lipid bilayer corresponds to the outer leaflet of the plasmalemma.

The major subcompartments of this system are anatomically discontinuous, but they remain functionally connected because membranous and lumenal material is moved from one compartment to another by means of transport vesicles. For example, proteins and phospholipids synthesized in the rough endoplasmic reticulum (the portion of the reticulum nearest the nucleus and studded with ribosomes) and the smooth endoplasmic reticulum are transported to the Golgi complex and then to secretory vesicles, which empty their contents when the vesicle membrane fuses with the

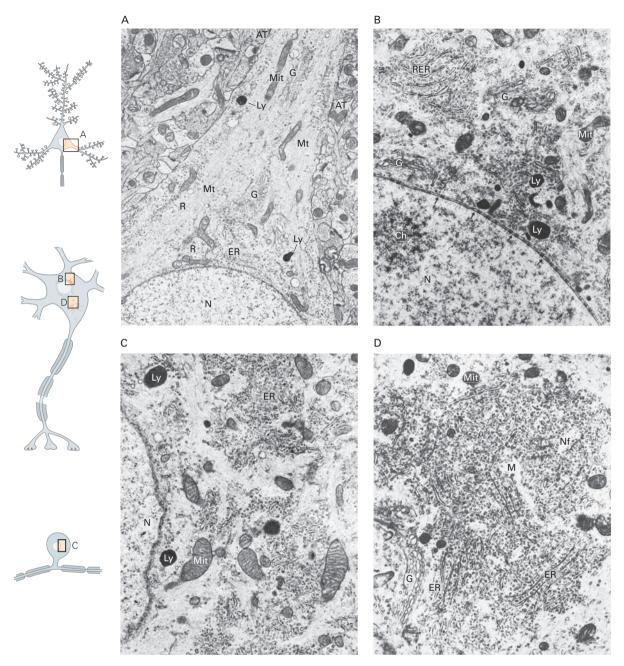

Figure 4–2 Organelles of the neuron. Electron micrographs show cytoplasm in four different regions of the neuron. (Adapted, with permission, from Peters et al. 1991.)

A. A dendrite emerges from a pyramidal neuron's cell body, which includes the endoplasmic reticulum (ER) above the nucleus (N) and a portion of the Golgi complex (G) nearby. Some Golgi cisternae have entered the dendrite, as have mitochondria (Mit), lysosomes (Ly), and ribosomes (R). Microtubules (Mt) are prominent cytoskeletal filaments in the cytosol. Axon terminals (AT) making contact with the dendrite are seen at the top and right.

B. Some components of a spinal motor neuron that participate in the synthesis of macromolecules. The nucleus (N), containing masses of chromatin (Ch), is bounded by the nuclear envelope, which contains many nuclear pores (arrows). The mRNA leaves the nucleus through these pores and attaches to ribosomes that either remain free in the cytoplasm or attach to the membranes of the endoplasmic reticulum to form the rough endoplasmic reticulum (RER). Regulatory proteins synthesized in the cytoplasm are imported into the nucleus through the

pores. Several parts of the Golgi apparatus (G) are seen, as are lysosomes (Ly) and mitochondria (Mit).

C-D. Micrographs of a dorsal root ganglion cell (C) and a motor neuron (D) show the organelles in the cell body that are chiefly responsible for synthesis and processing of proteins. The mRNA enters the cytoplasm through the nuclear envelope and is translated into proteins. Free polysomes, strings of ribosomes attached to a single mRNA, generate cytosolic proteins and proteins to be imported into mitochondria (Mit) and peroxisomes. Proteins destined for the endoplasmic reticulum are formed after the polysomes attach to the membrane of the endoplasmic reticulum (ER). The particular region of the motor neuron shown here also includes membranes of the Golgi apparatus (G), in which membrane and secretory proteins are further processed. Some of the newly synthesized proteins leave the Golgi apparatus in vesicles that move down the axon to synapses; other membrane proteins are incorporated into lysosomes (Ly) and other membranous organelles. The microtubules (M) and neurofilaments (Nf) are components of the cytoskeleton.

plasmalemma (a process called *exocytosis*). This secretory pathway serves to add membranous components to the plasmalemma and also to discharge any contents of the secretory vesicles into the extracellular space.

Conversely, plasmalemmal membrane is taken into the cell in the form of endocytic vesicles (*endocytosis*). These are incorporated into early endosomes, sorting compartments that are concentrated at the cell's periphery. The incorporated membrane, which typically contains specific proteins such as receptors, is then either shuttled back to the plasmalemma by vesicles for recycling or directed to late endosomes and eventually to mature lysosomes for degradation. (Exocytosis and endocytosis are discussed in detail later in this chapter and in Chapter 12.) The smooth endoplasmic reticulum also acts as a regulated internal Ca²⁺ store throughout the neuronal cytoplasm (see Chapter 11 on Ca²⁺ release).

A specialized portion of the rough endoplasmic reticulum forms the nuclear envelope, a spherical flattened cisterna that surrounds chromosomal DNA and its associated proteins (histones, transcription factors, polymerases, and isomerases) and defines the nucleus (Figure 4–1). Because the nuclear envelope is continuous with other portions of the endoplasmic reticulum and to the other membranes of the vacuolar apparatus, it is presumed to have evolved as an invagination of the plasmalemma to ensheathe eukaryotic chromosomes. The nuclear envelope is interrupted by nuclear pores, where fusion of the inner and outer membranes of the envelope results in the formation of hydrophilic channels through which proteins and RNA are exchanged between the cytoplasm proper and the nuclear cytoplasm.

Even though nucleoplasm and cytoplasm are continuous domains of cytosol, only molecules with molecular weights less than 5,000 can pass through the nuclear pores freely by diffusion. Larger molecules need help. Some proteins have special nuclear localization signals, domains that are composed of a sequence of basic amino acids (arginine and lysine) that are recognized by soluble proteins called *nuclear import receptors* (importins). At a nuclear pore this complex is guided into the nucleus by another group of proteins called *nucleoporins*.

The cytoplasm of the nerve cell body extends into the dendritic tree without functional differentiation. Generally, all organelles in the cytoplasm of the cell body are also present in dendrites, although the densities of the rough endoplasmic reticulum, Golgi complex, and lysosomes rapidly diminish with distance from the cell body. In dendrites the smooth endoplasmic reticulum is prominent at the base of thin processes called *spines* (Figures 4–3 and 4–4), the receptive portion of excitatory synapses. Concentrations of polyribosomes in dendritic spines are

presumed to serve local protein synthesis (see below and Figure 4–4).

In contrast to the continuity of the cell body and dendrites, a sharp functional boundary exists between the cell body at the axon hillock, where the axon emerges. Ribosomes, rough endoplasmic reticulum, and the Golgi complex—the organelles that comprise the main biosynthetic machinery for proteins in the neuron—are generally excluded from axons (see Figure 4–3). Lysosomes and certain proteins are also excluded. However, axons are rich in synaptic vesicles and their precursor membranes.

The Cytoskeleton Determines Cell Shape

The cytoskeleton determines the shape of a cell and is responsible for the asymmetric distribution of organelles within the cytoplasm. It includes three filamentous structures: microtubules, neurofilaments, and microfilaments. These filaments and associated proteins account for approximately a quarter of the total protein in the cell.

Microtubules form long scaffolds that extend from one end of a neuron to the other and play a key role in developing and maintaining cell shape. A single microtubule can be as long as 0.1 mm. Microtubules are constructed of protofilaments, each of which consists of multiple pairs of $\alpha\text{-}$ and $\beta\text{-}$ tubulin subunits arranged longitudinally along the microtubule (Figure 4–5A). Tubulin subunits bind to neighboring subunits along the protofilament and also laterally between adjacent protofilaments. The tubulin dimer has a polar structure: The negative end is oriented to the center of the cell while the positive end extends out to the periphery, to the dendrites and axon.

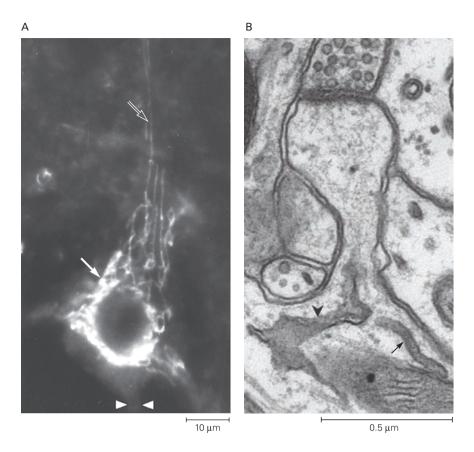

Microtubules grow by addition of guanosine triphosphate (GTP)-bound tubulin dimers at their positive end, the end that points to the periphery. Shortly after polymerization the GTP is hydrolyzed to guanosine diphosphate (GDP). When a microtubule stops growing, its positive end is capped by a GDP-bound tubulin monomer. Given the low affinity of the GDP-bound tubulin for the polymer, this would lead to catastrophic depolymerization unless the microtubules were stabilized by interaction with other proteins.

In fact, while microtubules undergo rapid cycles of polymerization and depolymerization in dividing cells, in mature dendrites and axons they are much more stable. This stability is caused by microtubule-associated proteins (MAPs) that promote the oriented polymerization and assembly of the tubulin polymers. MAPs in axons differ from those in dendrites. For example, MAP2

Figure 4–3 Golgi and endoplasmic reticulum membranes extend from the cell body into dendrites.

A. The Golgi complex (solid arrow) appears under the light microscope as several filaments that extend into the dendrites (open arrow) but not into the axon. The arrowheads at the bottom indicate the axon hillock. For this micrograph a large neuron of the brain stem was immunostained with antibodies specifically directed against the Golgi complex. (Reproduced, with permission, from De Camilli et al. 1986.)

B. Smooth endoplasmic reticulum (arrowhead) extends into the neck of a dendritic spine, while another membrane compartment sits at the origin of the spine (arrow). (Reproduced, with permission, from Cooney et al. 2002.)

is present in dendrites but not in axons, whereas tau and MAP3 are present. In Alzheimer disease and some other degenerative disorders tau proteins are modified and abnormally polymerized, forming a characteristic lesion called the *neurofibrillary tangle* (Box 4–1).

Tubulins are encoded by a multigene family. At least six genes code the α - and β -subunits. Because of the expression of the different genes or post transcriptional modifications more than 20 isoforms of tubulin are present in the brain.

Neurofilaments, 10 nm in diameter, are the bones of the cytoskeleton (see Figure 4–5B). They are the most abundant fibrillar component in axons; on average there are 3 to 10 times more neurofilaments than microtubules in an axon. Neurofilaments are related to intermediate filaments of other cell types, including the cytokeratins of epithelial cells (hair and nails), glial fibrillary acidic protein in astrocytes, and desmin in muscle. Unlike microtubules, neurofilaments are stable and almost totally polymerized in the cell.

At 3–7 nm in diameter microfilaments are the thinnest of the three main types of fibers that make up the cytoskeleton (Figure 4–5C). Like thin filaments of muscle, microfilaments are made up of two strands of

polymerized globular actin monomers, each bearing an ATP or adenosine diphosphate (ADP), wound into a double-stranded helix. Actin is a major constituent of all cells, perhaps the most abundant animal protein in nature. There are several closely related molecular forms: the α actin of skeletal muscle and at least two other molecular forms, β and γ . Each is encoded by a different gene. Neural actin in higher vertebrates is a mixture of the β and γ species, which differ from muscle actin by a few amino acid residues. Most actin molecules are highly conserved, not only in different cell types of a species but also in organisms as distantly related as humans and protozoa.

Unlike microtubules and neurofilaments, actin filaments are short. They are concentrated at the cell's periphery in the cortical cytoplasm just underneath the plasmalemma, where they form a dense network with many actin-binding proteins (eg, spectrin-fodrin, ankyrin, talin, and actinin). This matrix plays a key role in the dynamic function of the cell's periphery, such as the motility of growth cones (the growing tips of axons) during development, generation of specialized microdomains at the cell surface, and the formation of pre- and postsynaptic morphological specializations.

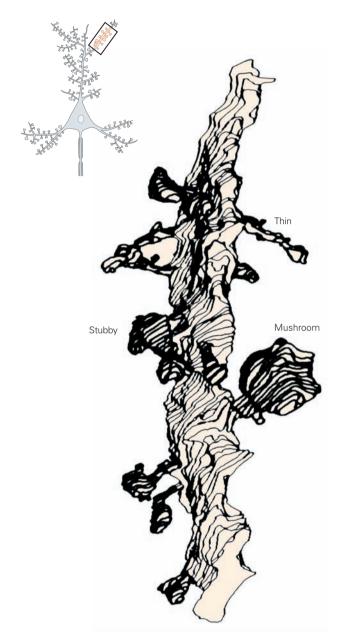

Figure 4–4 Types of dendritic spines. Three types of dendritic spine shapes are shown in a mature dendrite in a pyramidal cell in the CA1 region of the hippocampus. The drawing is based on a series of electron micrographs. (Reproduced, with permission, from Harris and Stevens 1989.)

A. In this thin dendritic spine the thickened receptive surface (open arrow), located across from the presynaptic axon, contains synaptic receptors. The tissue shown here and in B and C is from the hippocampus of a postnatal day-15 rat brain.

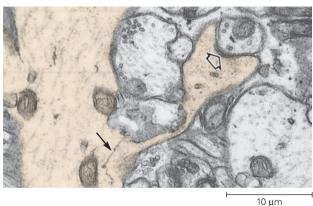

A Thin

B Stubby

C Mushroom

- **B.** Stubby spines containing postsynaptic densities (arrow) are both small and rare in the mature hippocampus. Their larger counterparts (not shown) predominate in the immature brain.
- C. Mushroom-shaped spines have a larger head. The immature spine shown here contains flat cisternae of smooth endoplasmic reticulum, some with a beaded appearance (solid arrow). The postsynaptic density is indicated by the open arrow. (A, B, and C are reproduced, with permission, from Sorra and Harris 1993.)

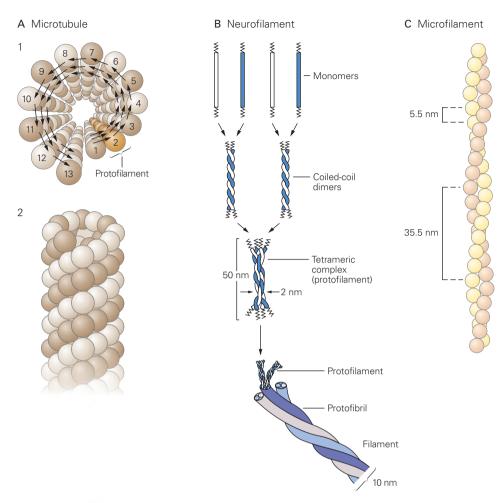

Figure 4-5 Atlas of fibrillary structures.

A. Microtubules, the largest-diameter fibers (25 nm), are helical cylinders composed of 13 protofilaments, each 5 nm in width. Each protofilament is made up of a column of alternating α - and β -tubulin subunits (each subunit has a molecular weight of approximately 50,000). Adjacent subunits bind to each along the longitudinal protofilaments and laterally between subunits of adjacent protofilaments.

A tubulin molecule is a heterodimer consisting of one α - and one β -tubulin subunit. 1. View of a microtubule. The arrows indicate the direction of the right-handed helix. 2. A side-view of a microtubule shows the alternating α - and β -subunits.

B. Neurofilaments are built with fibers that twist around each other to produce coils of increasing thickness. The thinnest

units are monomers that form coiled-coil heterodimers. These dimers form a tetrameric complex that becomes the protofilament. Two protofilaments become a protofibril, and three protofibrils are helically twisted to form the 10 nm diameter neurofilament. (Adapted, with permission, from Bershadsky and Vasiliev 1988.)

C. Microfilaments, the smallest diameter fibers (approximately 7 nm), are composed of two strands of polymerized globular actin (G-actin) monomers arranged in a helix. At least six different (but closely related) actins are found in mammals. Each variant is encoded by a separate gene. Microfilaments are polar structures because the globular monomers are asymmetric.

Like microtubules, microfilaments undergo cycles of polymerization and depolymerization. At any one time approximately half the total actin in a cell can exist as unpolymerized monomers. The state of actin is controlled by binding proteins, which facilitate assembly and limit polymer length by capping the rapidly growing end of the filament or by severing it. Other

binding proteins crosslink or bundle microfilaments. The dynamic state of microtubules and microfilaments permits a mature neuron to retract old axons and dendrites and extend new ones. This structural plasticity is thought to be a major factor in changes of synaptic connections and efficacy, and therefore cellular mechanisms of long-term memory and learning.

Box 4-1 Abnormal Accumulations of Proteins Are Hallmarks of Many Neurological Disorders

Tau is a microtubule-binding protein normally present in nerve cells. In Alzheimer disease abnormal aggregates of tau are visible in the light microscope in neurons and glia as well as in the extracellular space. Highly phosphorylated tau molecules arranged in long, thin polymers wind around one another to form paired helical filaments (Figure 4–6A and see Chapter 59). Bundles of the polymers, known as *neurofibrillary tangles*, accumulate in neuronal cell bodies, dendrites, and axons (Figure 4–6A).

In normal neurons tau is either bound to microtubules or free in the cytosol. In the tangles it is not bound to microtubules but is highly insoluble. The tangles form at least in part because tau is not proteolytically degraded. The accumulations disturb the polymerization of tubulin and therefore interfere with axonal transport. Consequently, the shape of the neuron is not maintained.

Tau accumulations are also found in neurons of patients with progressive supranuclear palsy, a movement disorder, and in patients with frontotemporal dementias, a group of neurodegenerative disorders that affect the frontal and temporal lobes (see Chapter 59). The familial forms of fronto temporal dementias are caused by mutations in the *tau* gene. Abnormal aggregates are also found in glial cells, both astrocytes and oligodendrocytes, in progressive supranuclear palsy, cortico-basoganglionic degeneration, and fronto temporal dementias.

The peptide β -amyloid also accumulates in the extracellular space in Alzheimer disease (Figure 4–6B and see Chapter 57). It is a small proteolytic product of a much larger integral membrane protein, amyloid precursor protein, which is normally processed by several proteolytic enzymes associated with intracellular membranes. The

proteolytic pathway that generates β -amyloid requires the enzyme β -secretase.

For unknown reasons, in Alzheimer disease abnormal amounts of the amyloid precursor are processed by β -secretase. Some patients with early-onset familial Alzheimer disease either have mutations in the amyloid precursor gene or in the genes coding for the membrane proteins presentil 1 and 2, which are closely associated with β -secretase activity.

In Parkinson disease abnormal aggregates of α -synuclein accumulate in cell bodies of neurons. Like tau, α -synuclein is a normal soluble constituent of the cell. But in Parkinson disease it becomes insoluble, forming spherical inclusions called *Lewy bodies* (Figure 4–6C and see Chapter 44).

These abnormal inclusions also contain ubiquitin. Because ubiquitin is required for proteasomal degradation of proteins, its presence suggests that affected neurons have attempted to target α -synuclein or other molecular constituents for proteolysis. Apparently, degradation does not occur, possibly because of misfolding or the abnormal aggregation of the proteins or because of faulty proteolytic processing in the cell.

Do these abnormal protein accumulations affect the physiology of the neurons and glia? On the one hand, the accumulations may form in response to altered post-translational processing of the proteins and serve to isolate the abnormal proteins, permitting normal cell activities. On the other hand, the accumulations may disrupt cellular activities such as membrane trafficking and axonal and dendritic transport. In addition, the altered proteins themselves, aside from the aggregations, may have deleterious effects. With β -amyloid there is evidence that the peptide itself is toxic.

In addition to serving as cytoskeleton, microtubules and actin filaments act as tracks along which organelles and proteins are rapidly driven by molecular motors. The motors used by the actin filaments, the *myosins*, also mediate other types of cell motility, including extension of the cell's processes, and the translocation of membranous organelles from the bulk cytoplasm to the region adjacent to the plasma membrane. (Actomyosin is responsible for muscle contraction.) Because the microtubules and actin filaments are polar, each motor drives its organelle cargo in only one direction.

As already mentioned, microtubules are arranged in parallel in the axon with positive ends pointing away from the cell body and negative ends facing the cell body. This regular orientation permits some organelles to move toward nerve endings and others to move away from nerve endings, the direction being determined by the specific type of molecule motor, thus maintaining the distinctive distribution of axonal organelles (Figure 4–7). In dendrites, however, microtubules with opposite polarities are mixed together, explaining why the organelles of the cell body and dendrites are similar.

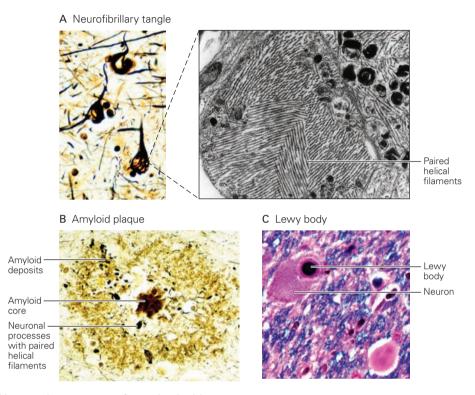

Figure 4–6 Abnormal aggregates of proteins inside neurons in Alzheimer and Parkinson diseases.

A. Intracellular neurofibrillary tangles of Alzheimer disease, labeled here with a dark silver stain (left). (Reproduced, with permission, from J.P. Vonsattel.) The electron micrograph of a tangle (right) shows the bundles of abnormal filaments, here filling a dendrite. The filaments are composed of altered tau protein. (Reproduced, with permission, from Esiri et al. 2002.)

B. Extracellular deposits of polymerized β -amyloid peptides in Alzheimer disease create an amyloid plaque. This plaque has a dense core of amyloid as well as a surrounding halo of deposits. Note the neuronal processes in the plaque with tangle pathology. (Reproduced, with permission, from J.P. Vonsattel.)

C. A Lewy body in the substantia nigra of a patient with Parkinson disease contains accumulations of abnormal filaments made up of α -synuclein, among other proteins. (Reproduced, with permission, from J.P. Vonsattel.)

Protein Particles and Organelles Are Actively Transported Along the Axon and Dendrites

In neurons most proteins are made in the cell body from mRNAs in the cell body. Important examples are synthesis of neurotransmitter biosynthetic enzymes, synaptic vesicle membrane components, and neurosecretory peptides. Because axons and terminals often lie at great distances from the cell body, transport mechanisms are crucial for sustaining the function of these remote regions.

The axon terminal, the site of secretion most important for neuronal signaling, is considerably distant from the cell body. For example, in a motor neuron that innervates a muscle of the leg in humans, the distance of the nerve terminal from the cell body can exceed 10,000 times the cell-body diameter. Passive diffusion is far too slow to deliver vesicles, particles, or even single macromolecules over this great distance. Membrane and secretory products formed in the cell body must be actively transported to the end of the axon (Figure 4–8).

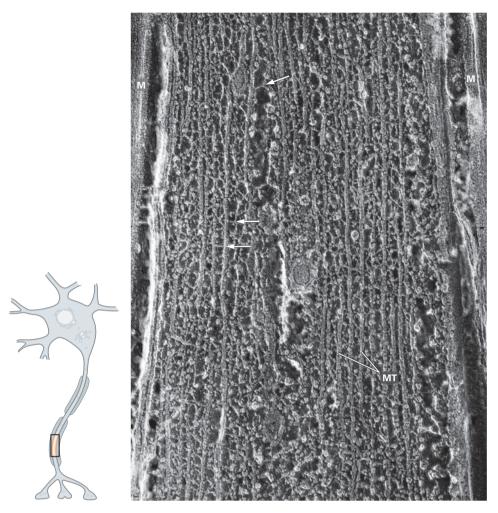

Figure 4–7 The cytoskeletal structure of an axon. The micrograph shows the dense packing of microtubules and neurofilaments linked by cross bridges (arrows). Organelles are transported in both the anterograde and retrograde directions

in the microtubule-rich domains. Visualization in the micrograph was achieved by quick freezing and deep etching. **M**, myelin sheath; **MT**, microtubules × 105,000. (Adapted, with permission, from Schnapp and Reese 1982.)

In 1948 Paul Weiss first demonstrated axonal transport when he tied off a sciatic nerve and observed that axoplasm in the nerve accumulated with time on the proximal side of the ligature. He concluded that axoplasm moves at a slow, constant rate from the cell body toward terminals in a process he called *axoplasmic flow*. Today we know that the flow Weiss observed consists of two discrete mechanisms, one fast and the other slow.

Membranous organelles move toward terminals (anterograde direction) and back toward the cell body (retrograde direction) by *fast axonal transport*, a form of transport that is faster than 400 mm per day in warm-blooded animals. In contrast, cytosolic and cytoskeletal proteins move only in the anterograde direction by a much slower form of transport, *slow*

axonal transport. These transport mechanisms in neurons are adaptations of processes that facilitate intracellular movement of organelles in all secretory cells. Because these mechanisms all operate along axons, they have been used by neuroanatomists to trace the axon distribution of neurons (Box 4–2).

Fast Axonal Transport Carries Membranous Organelles

Large membranous organelles are carried to and from the axon terminals by fast transport (Figure 4–10). These organelles include synaptic vesicle precursors, large dense-core vesicles, mitochondria, elements of the smooth endoplasmic reticulum, as well as protein

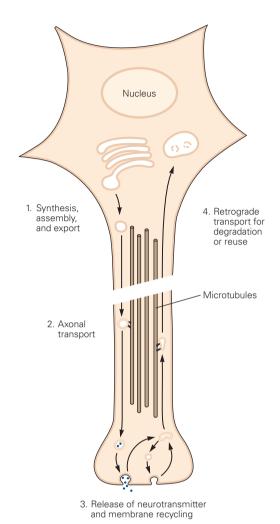

Figure 4–8 Membrane trafficking in the neuron. 1. Proteins and lipids of secretory organelles are synthesized in the endoplasmic reticulum and transported to the Golgi complex, where large dense-core vesicles (peptide-containing secretory granules) and synaptic vesicle precursors are assembled. 2. Large dense-core vesicles and transport vesicles that carry synaptic vesicle proteins travel down the axon via axonal transport.

3. At the nerve terminals the synaptic vesicles are assembled and loaded with nonpeptide neurotransmitters. Synaptic vesicles and large dense-core vesicles release their contents by exocytosis. 4. Following exocytosis, large dense-core vesicle membranes are returned to the cell body for reuse or degradation. Synaptic vesicle membranes undergo many cycles of local exocytosis and endocytosis in the presynaptic terminal.

particles carrying RNAs. Direct microscopic analysis reveals that fast transport occurs in a stop-and-start (saltatory) fashion along linear tracks of microtubules aligned with the main axis of the axon. The saltatory nature of the movement results from the periodic

dissociation of an organelle from the track or from collisions with other particles.

Early experiments on dorsal root ganglion cells showed that anterograde fast transport depends critically on ATP, is not affected by inhibitors of protein synthesis (once the labeled amino acid injected is incorporated), and does not depend on the cell body, because it occurs in axons severed from their cell bodies. In fact, active transport can occur in reconstituted cell-free axoplasm.

Microtubules provide an essentially stationary track on which specific organelles can be moved by molecular motors. The idea that microtubules are involved in fast transport emerged from the finding that certain alkaloids that disrupt microtubules and block mitosis, which depends on microtubules, also interfere with fast transport.

Molecular motors were first visualized in electron micrographs as cross bridges between microtubules and moving particles (Figure 4–7). The motor molecules for anterograde transport (toward the positive end of microtubules) are *kinesin* and a variety of kinesin-related proteins. The kinesins represent a large family of adenosine triphosphatases (ATPase), each of which transports different cargoes. Kinesin is a heterotetramer composed of two heavy chains and two light chains. Each heavy chain has three domains: (1) a globular head (the ATPase domain) that acts as the motor when attached to microtubules, (2) a coiled-coil helical stalk responsible for dimerization with the other heavy chain, and (3) a fan-like carboxyl-terminus that interacts with the light chains.

The organelles moved by retrograde fast transport are primarily endosomes generated by endocytic activity at nerve endings, mitochondria, and elements of the endoplasmic reticulum. Many of these components degrade in lysosomes. Retrograde fast transport also delivers signals that regulate gene expression in the neuron's nucleus. For example, activated growth factor receptors are taken up into vesicles at nerve endings and carried back along the axon to their site of action in the nucleus. Transport of transcription factors informs the gene transcription apparatus in the nucleus of conditions in the periphery. Retrograde transport of these molecules is especially important during nerve regeneration and axon regrowth (see Chapter 54). Certain toxins (tetanus toxin) as well as pathogens (herpes simplex, rabies, and polio viruses) are also transported toward the cell body along the axon.

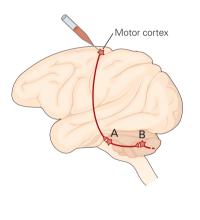

The rate of retrograde fast transport is approximately one-half to two-thirds that of anterograde fast transport. As in anterograde transport, particles move along microtubules. The motor molecule for retrograde transport is a microtubule-associated ATPase called MAP-1C. This molecule is similar to the dyneins

Box 4–2 Neuroanatomical Tracing Makes Use of Axonal Transport

Neuroanatomists typically locate axons and terminals of specific nerve cell bodies by microinjection of dyes; expression of fluorescent proteins; or autoradiographically tracing specific proteins soon after administering radioactively labeled amino acids, certain labeled sugars (fucose or amino sugars, precursors of glycoprotein), or specific transmitter substances.

Similarly, particles, proteins, or dyes that are readily taken up at nerve terminals by endocytosis and transported back to cell bodies are used to identify the cell bodies. The enzyme horseradish peroxidase has been most widely used for this type of study because it readily undergoes retrograde transport and its reaction product is conveniently visualized histochemically.

Axonal transport is also used by neuroanatomists to label material exchanged between neurons, making it possible to identify neuronal networks (Figure 4–9).

A Pontine nuclei

Figure 4–9 Axonal transport of the herpes simplex virus (HSV) is used to trace cortical pathways in monkeys. Depending on the strain, the virus moves in the anterograde or retrograde direction by axonal transport. In either direction it enters a neuron with which the infected cell makes synaptic contact. Here the projections of cells in the primary motor cortex to the cerebellum in monkeys were traced using an anterograde-moving strain (HSV-1

[H129]). Monkeys were injected in the region of the primary motor cortex that controls the arm. After 4 days the brain was sectioned and immunostained for viral antigen. Micrographs show the virus was transported from the primary motor cortex to second-order neurons in pontine nuclei (A) and then to third-order neurons in the cerebellar cortex (B). (Reproduced, with permission, from P. L. Strick.)

in cilia and flagella of other cells and consists of a multimeric protein complex with two globular heads on two stalks connected to a basal structure. The globular heads attach to microtubules and act as motors, moving toward the negative end of the polymer. As with kinesin, the other end of the complex attaches to the organelle being moved.

Microtubules also transport mRNAs and ribosomal RNA carried in particles formed with RNA-binding

proteins. These proteins have been characterized in both vertebrate and invertebrate nervous systems and include the cytoplasmic polyadenylation element binding protein (CPEB), the fragile X protein, Hu proteins, NOVA, and Staufen. The activities of these proteins are critical. Humans with mutations in the fragile X gene are mentally retarded and have spinal defects. For example, CPEB keeps select mRNAs dormant during transport from the cell body to nerve endings;

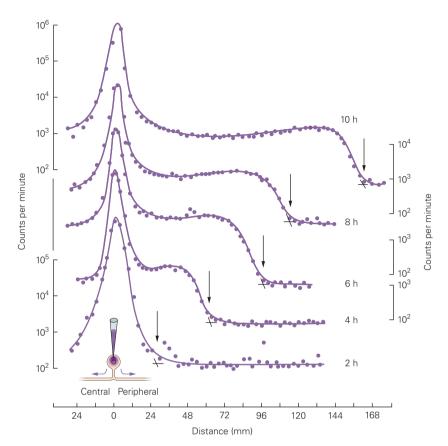

Figure 4–10 Early experiments on anterograde axonal transport used radioactive labeling of proteins. In the experiment illustrated here the distribution of radioactive proteins along the sciatic nerve of the cat was measured at various times after injection of [³H]-leucine into dorsal root ganglia in the lumbar region of the spinal cord. To show transport curves from various times (2, 4, 6, 8, and 10 hours after the injection) in one figure, several ordinate scales (in logarithmic units) are used. Large amounts of labeled protein stay in the ganglion cell bodies but,

with time, move out along axons in the sciatic nerve, so the advancing front of the labeled protein is progressively farther from the cell body (black arrows). The velocity of transport can be calculated from the distances of the front displayed at the various times. From experiments of this kind Sidney Ochs found that the rate of fast axonal transport is constant at 410 mm per day at body temperature. (Adapted, with permission, from Ochs 1972.)

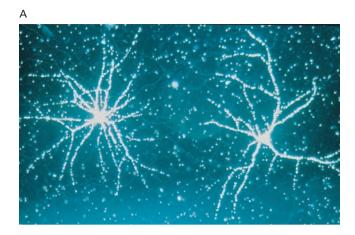

once there (upon stimulation), the binding protein can facilitate the local translation of the RNA by mediating polyadenylation and activation of the messenger. Both CPEB and Staufen were discovered in *Drosophila* where they maintain maternal mRNAs dormant in unfertilized eggs and, upon fertilization, distribute and localize mRNA to various regions of the dividing embryo.

Proteins, ribosomes, and mRNA are concentrated at the base of dendritic spines (Figure 4–11). Only a select group of mRNA are transported to the nerve terminals. These include mRNA for actin- and cytoskeletal-associated proteins MAP2 and the α -subunit of the Ca $^{2+}$ /calmodulin-dependent protein kinase. They are translated in the dendrites in response to activity in a presynaptic neuron. This local protein synthesis is

thought to be important in sustaining the molecular changes at the synapse that underlie long-term memory and learning. Likewise, the mRNA for myelin basic protein is transported to the distant ends of the oligodendrocytes, where it is translated as the myelin sheath grows, as discussed later in this chapter.

Slow Axonal Transport Carries Cytosolic Proteins and Elements of the Cytoskeleton

Cytosolic proteins and cytoskeletal proteins are moved from the cell body by slow axonal transport. Slow transport occurs only in the anterograde direction and consists of at least two kinetic components that carry different proteins at different rates.

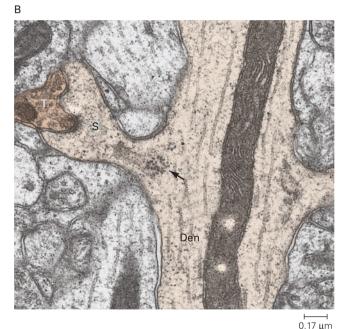

Figure 4–11 Ribosomes in the dendritic arbor. (Images reproduced, with permission, from Oswald Steward.)

A. Some ribosomes are dispatched from the cell body to dendrites where they are used in local protein synthesis. This autoradiograph shows the distribution of ribosomal RNA (rRNA) in hippocampal neurons in low-density cultures using in situ hybridization. The photomicrograph was taken with dark field illumination, in which silver grains reflect light and thus appear as bright spots. Silver grains, denoting the rRNA, are heavily concentrated over cell bodies and dendrites but are not detectable over the axons that crisscross among the dendrites.

B. Ribosomes in dendrites are selectively concentrated at the junction of the spine and main dendritic shaft (arrow), where the spine contacts the axon terminal of a presynaptic neuron. This electron micrograph shows a mushroom-shaped spine of a neuron in the hippocampal dentate gyrus. Note the absence of ribosomes in the dendritic shaft. S, spine head; T, presynaptic terminal; **Den**, main shaft of the dendrite containing a long mitochondrion. × 60,000.

The slower component travels at 0.2 to 2.5 mm per day and carries the proteins that make up the fibrillar elements of the cytoskeleton: the subunits of neurofilaments and α - and β -tubulin subunits of microtubules. These fibrous proteins constitute approximately 75% of the total protein moved in the slower component. Microtubules are transported in polymerized form by a mechanism involving microtubule sliding in which relatively short preassembled microtubules move along existing microtubules. Neurofilament monomers or short polymers move passively together with the microtubules because they are cross-linked by protein bridges.

The other component of slow axonal transport is approximately twice as fast as the slower. It carries clathrin, actin, and actin-binding proteins as well as a variety of enzymes and other proteins.

Proteins Are Made in Neurons as in Other Secretory Cells

Secretory and Membrane Proteins Are Synthesized and Modified in the Endoplasmic Reticulum

The mRNAs for secretory and membrane proteins are translated in conjunction with the membrane of the rough endoplasmic reticulum, and their polypeptide products are processed extensively within the lumen of the endoplasmic reticulum. Most polypeptides destined to become proteins are translocated across the membrane of the rough endoplasmic reticulum during synthesis, a process called *cotranslational transfer*.

Transfer is possible because ribosomes, the site where proteins are synthesized, attach to the cytosolic surface of the reticulum (Figure 4–12). Complete transfer of the polypeptide chain into the lumen of the reticulum produces a secretory protein (recall that the inside of the reticulum is related to the outside of the cell). Important examples are the neuroactive peptides. If the transfer is incomplete, an integral membrane protein results. Because a polypeptide chain can thread its way through the membrane many times during synthesis, several membrane-spanning configurations are possible depending on the primary amino acid sequence of the protein. Important examples are neurotransmitter receptors and ion channels (see Chapter 5).

Some proteins transported into the endoplasmic reticulum remain there. Others are moved to other compartments of the vacuolar apparatus or to the plasmalemma, or are secreted into the extracellular space. Proteins that are processed in the endoplasmic reticulum are extensively modified. One important modification is the formation of intramolecular disulfide

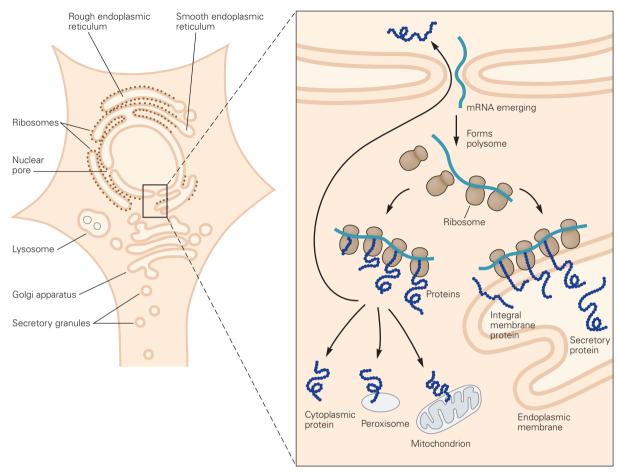

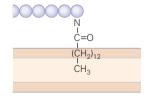

Figure 4–12 Protein synthesis in the endoplasmic reticulum. Free and membrane-bound polysomes translate mRNA that encodes proteins with a variety of destinations. Messenger RNA, transcribed from genomic DNA in the neuron's nucleus,

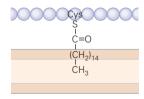

emerges into the cytoplasm through nuclear pores (enlargement) to form polyribosomes. The polypeptides that become secretory and membrane proteins are translocated across the membrane of the rough endoplasmic reticulum.

linkages (Cys-S-S-Cys) caused by oxidation of pairs of free sulfhydryl side chains, a process that cannot occur in the reducing environment of the cytosol. Disulfide linkages are crucial to the tertiary structure of these proteins.

Proteins may be modified by cytosolic enzymes either during synthesis (cotranslational modification) or afterward (post-translational modification). One example is N-acylation, the transfer of an acyl group to the N-terminus of the growing polypeptide chain. Acylation by a 14-carbon fatty acid myristoyl group permits the protein to anchor in membranes through the lipid chain.

Other fatty acids can be conjugated to the sulfhydryl group of cysteine, producing a thioacylation:

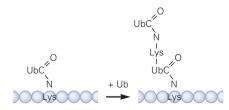

Isoprenylation is another post-translational modification important for anchoring proteins to the cytosolic side of membranes. It occurs shortly after synthesis of the protein is completed and involves a series of enzymatic steps that result in thioacylation by one of two long-chain hydrophobic polyisoprenyl moieties (farnesyl, with 15 carbons, or geranyl-geranyl, with 20) of the sulfhydryl group of a cysteine at the C-terminus of proteins.

Some post-translational modifications are readily reversible and thus used to regulate the function of a protein transiently. The most common of these modifications is the phosphorylation at the hydroxyl group in serine, threonine, or tyrosine residues by protein kinases. Dephosphorylation is catalyzed by protein phosphatases. (These reactions are discussed in Chapter 11.) As with all post-translational modifications, the sites to be phosphorylated are determined by particular sequences of amino acids around the residue to be modified. Phosphorylation can alter physiological processes in a reversible fashion. For example, protein phosphorylation-dephosphorylation reactions regulate the kinetics of ion channels, the activity of transcription factors, and the assembly of the cytoskeleton.

Still another important post-translational modification is the addition of ubiquitin, a highly conserved protein with 76 amino acids, to the ∈-amino group of specific lysine residues in the protein molecule. Ubiquitination, which regulates protein degradation, is mediated by three enzymes. E1 is an activating enzyme that uses the energy of ATP. The activated ubiquitin is next transferred to a conjugase, E2, which then transfers the activated moiety to a ligase, E3. E3 alone or together with the E2 transfers the ubiquitinyl group to the lysine residue in a protein. Specificity arises because a given protein molecule can only be ubiquinated by a specific E3 or combination of E3 and E2. Some E3s also require special cofactors—ubiquitination occurs only in the presence of E3 and a cofactor protein.

Monoubiquitination tags a protein for degradation in the endosomal-lysosomal system. This is especially important in endocytosis and recycling of surface receptors. Ubiquitinyl monomers are successively linked to the ∈-amino group of a lysine residue in the previously added ubiquitin moiety. Addition of more than five ubiquitins to the multiubiquitin chain tags the protein for degradation by the proteasome, a large complex containing multifunctional protease subunits that cleave proteins into short peptides.

The ATP-ubiquitin-proteasome pathway is a mechanism for the selective and regulated proteolysis of proteins that operates in the cytosol of all regions of the neuron—dendrites, cell body, axon, and terminals.

Until recently this process was thought to be primarily directed to poorly folded, denatured, or aged and damaged proteins. We now know that ubiquitin-mediated proteolysis can be regulated by neuronal activity and plays specific roles in many neuronal processes, including synaptogenesis and long-term memory storage.

Another important protein modification is glycosylation, which occurs on amino groups of asparagine residues (N-linked glycosylation) and results in the addition en bloc of complex polysaccharide chains. These chains are then trimmed within the endoplasmic reticulum by a series of reactions controlled by chaperones, including heat shock proteins, calnexin, and calreticulin. Because of the great chemical specificities of oligosaccharide moieties, these modifications can have important implications for cell function. For example, cell-to-cell interactions that occur during development rely on molecular recognition between glycoproteins on the surfaces of the two interacting cells. Also, because a given protein can have somewhat different oligosaccharide chains, glycosylation can diversify the function of a protein. It can increase the hydrophilicity of the protein (useful for secretory proteins), fine-tune its ability to bind macromolecular partners, and delay its degradation.

An interesting post-translational modification of mRNA is RNA interference (RNAi), the targeted destruction of double-stranded RNAs. This mechanism, which is believed to have arisen to protect cells against viruses and other rogue fragments of nucleic acids, shuts down the synthesis of any targeted protein. Double-stranded RNAs are taken up by an enzyme complex that cleaves the molecule into oligomers. The RNA sequences are retained by the complex. As a result, any homologous hybridizing RNA strands, either double- or single-stranded, will be destroyed. The process is regenerative: The complex retains a hybridizing fragment and goes on to destroy another RNA molecule until none remain in the cell. Although the physiological role of RNA interference (RNAi) in normal cells is unclear, transfection or injection of RNAi into cells is of great research and clinical importance (see Chapter 3).

Secretory Proteins Are Modified in the Golgi Complex

Proteins from the endoplasmic reticulum are carried in transport vesicles to the Golgi complex where they are modified and then moved to synaptic terminals and other parts of the plasmalemma. The Golgi complex appears as a grouping of membranous sacks aligned with one another in long ribbons.

The mechanism by which vesicles are transported between stations of the secretory and endocytic

pathways is remarkably conserved from simple unicellular prokaryotes (yeast) to neurons and glia of multicellular organisms. Transport vesicles develop from membrane, beginning with the assembly of proteins that form *coats*, or coat proteins, at selected patches of the cytosolic surface of the membrane. A coat has two functions. It forms rigid cage-like structures that produce evagination of the membrane into a bud shape and it selects the protein cargo to be incorporated into the vesicles.

There are several types of coats. Clathrin coats assist in evaginating Golgi complex membrane and plasmalemma during endocytosis. Two other coats, COPI and COPII, cover transport vesicles that shuttle between the endoplasmic reticulum and the Golgi complex. Coats usually are rapidly dissolved once free vesicles have formed. The fusion of vesicles with the target membrane is mediated by a cascade of molecular interactions, the most important of which is the reciprocal recognition of small proteins on the cytosolic surfaces of the two interacting membranes: vesicular soluble N-ethylmaleimide-sensitive factor attachment protein receptors (v-SNAREs) and t-SNAREs (target-membrane SNAREs). The actions of these small proteins are discussed in Chapter 12 in connection with how synaptic vesicles release neurotransmitters at synapses.

Vesicles from the endoplasmic reticulum arrive at the cis side of the Golgi complex (the aspect facing the nucleus) and fuse with its membranes to deliver their contents into the Golgi complex. These proteins travel from one Golgi compartment (cisterna) to the next, from the cis to the trans side, undergoing a series of enzymatic reactions. Each Golgi cisterna or set of cisternae is specialized for a particular type of reaction. Several types of protein modifications, some of which begin in the endoplasmic reticulum, occur within the Golgi complex proper or within the transport station adjacent to its trans side, the trans-Golgi network (the aspect of the complex typically facing away from the nucleus toward the axon hillock). These modifications include the addition of N-linked oligosaccharides, O-linked (on the hydroxyl groups of serine and threonine) glycosylation, phosphorylation, and sulfation.

Both soluble and membrane-bound proteins that travel through the Golgi complex emerge from the trans-Golgi network in a variety of vesicles that have different molecular compositions and destinations. Proteins transported from the trans-Golgi network include secretory products as well as newly synthesized components for the plasmalemma, endosomes, and other membranous organelles (see Figure 4–1). One class of vesicles carries newly synthesized plasmalemmal proteins and proteins that are continuously secreted (*constitutive*

secretion). These vesicles fuse with the plasmalemma in an unregulated fashion. An important type of these vesicles delivers lysosomal enzymes to late endosomes.

Still other classes of vesicles carry secretory proteins that are released by an extracellular stimulus (regulated secretion). One type stores secretory products, primarily neuroactive peptides in high concentrations. Called *large dense-core vesicles* because of their electron-dense (osmophilic) appearance in the electron microscope, these vesicles are similar in function and biogenesis to peptide-containing granules of endocrine cells. Large dense-core vesicles are targeted primarily to axons but can be seen in all regions of the neuron. They accumulate in the cytoplasm just beneath the plasma membrane and are highly concentrated at axon terminals, where they undergo Ca²⁺-regulated exocytosis (see Figure 4–8). The optimal stimulus for their secretion is a train of action potentials.

An important, but as yet unanswered, question is how synaptic vesicles—the small lucent vesicles responsible for the rapid release of neurotransmitter at axon terminals—reach the terminals. It is thought that proteins that make up synaptic vesicles are carried to endosomes and the plasmalemma of axon terminals in large precursor vesicles from the trans-Golgi network. Once at the terminals the proteins are processed into synaptic vesicles as they pass through endosomes during the exocytosis/recycling process described in Chapter 12. The neurotransmitter molecules stored in synaptic vesicles are released by exocytosis regulated by Ca²⁺ influx through channels close to the release site.

Surface Membrane and Extracellular Substances Are Recycled in the Cell

Vesicular traffic toward the cell surface is continuously balanced by *endocytic traffic* from the plasmalemma to internal organelles. This traffic is essential for maintaining the area of the plasmalemma in a steady state. It can alter the activity of many important regulatory molecules on the cell surface (eg, by removing receptors and adhesion molecules). It also removes nutrients and molecules, such as expendable receptor ligands and damaged membrane proteins, to the degradative compartments of the cells. Finally, it serves to recycle synaptic vesicles at nerve terminals (see Chapter 12).

A significant fraction of endocytic traffic is carried in clathrin-coated vesicles. The clathrin coat interacts selectively through transmembrane receptors with extracellular molecules that are to be taken up into the cell. For this reason clathrin-mediated uptake is often referred to as *receptor-mediated endocytosis*. The vesicles eventually shed their clathrin coats and fuse with the early endosomes, in which proteins to be recycled to the cell surface are separated from those destined for other intracellular organelles. Patches of the plasmalemma can also be recycled through larger, uncoated vacuoles that also fuse with early endosomes (*bulk endocytosis*).

Glial Cells Play Diverse Roles in Neural Function

Glia Form the Insulating Sheaths for Axons

A major function of oligodendrocytes and Schwann cells is to provide the insulating material that allows rapid conduction of electrical signals along the axon. These cells produce thin sheets of myelin that wrap concentrically, many times, around the axon. Central nervous system myelin, produced by oligodendrocytes, is similar, but not identical to peripheral nervous system myelin, produced by Schwann cells.

Both types of glia produce myelin only for segments of axons. This is because the axon is not continuously wrapped in myelin, a feature that facilitates propagation of action potentials (see Chapter 6). One Schwann cell produces a single myelin sheath for one segment of one axon, whereas one oligodendrocyte produces myelin sheaths for segments of as many as 30 axons (Figure 4–13).

The number of layers of myelin on an axon is proportional to the diameter of the axon—larger axons have thicker sheaths. Axons with very small diameters are not myelinated; nonmyelinated axons conduct action potentials much more slowly than do myelinated axons because of their smaller diameter and lack of myelin insulation (see Chapter 6).

The regular lamellar structure and biochemical composition of the sheath are consequences of how myelin is formed from the glial plasma membrane. In the development of the peripheral nervous system, before myelination takes place, the axon lies within a trough formed by Schwann cells. Schwann cells line up along the axon at regular intervals that become the myelinated segments of axon. The external membrane of each Schwann cell surrounds the axon to form a double membrane structure called the *mesaxon*, which elongates and spirals around the axon in concentric layers (Figure 4–13C). As the axon is ensheathed, the cytoplasm of the Schwann cell is squeezed out to form a compact lamellar structure.

The regularly spaced segments of myelin sheath are separated by unmyelinated gaps, called *nodes of Ranvier*,

where the plasma membrane of the axon is exposed to the extracellular space for approximately 1 μm (Figure 4–14). This arrangement greatly increases the speed at which nerve impulses are conducted (up to 100 m/s in humans) because the signal jumps from one node to the next, a mechanism called *saltatory conduction* (see Chapter 6). Nodes are easily excited because they have a low threshold. In the axon membrane at the nodes the density of Na⁺ channels, which generate the action potential, is approximately 50 times greater than in myelin-sheathed regions of membrane. Several cell adhesion molecules in the paranodal regions keep the myelin boundaries stable.

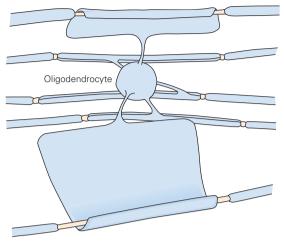

In the human femoral nerve the primary sensory axon is approximately 0.5 m long and the internodal distance is 1 to 1.5 mm; thus approximately 300 to 500 nodes of Ranvier occur along a primary afferent fiber between the thigh muscle and the cell body in the dorsal root ganglion. Because each internodal segment is formed by a single Schwann cell, as many as 500 Schwann cells participate in the myelination of each peripheral sensory axon.

Myelin has bimolecular layers of lipid interspersed between protein layers. Its composition is similar to that of the plasmalemma, consisting of 70% lipid and 30% protein with high concentrations of cholesterol and phospholipid. In the central nervous system myelin has two major proteins: myelin basic protein, a small, positively charged protein that is situated on the cytoplasmic surface of compact myelin, and proteolipid protein, a hydrophobic integral membrane protein. Presumably, both provide structural stability for the sheath. Both have also been implicated as important autoantigens against which the immune system can react to produce the demyelinating disease, multiple sclerosis. In the peripheral nervous system myelin contains a major protein, P₀, as well as the hydrophobic protein PMP22. Autoimmune reactions to these proteins produce a demyelinating peripheral neuropathy, the Guillain-Barré syndrome. Mutations in myelin protein genes also cause a variety of demyelinating diseases in both peripheral and central axons (Box 4–3). Demyelination slows down, or even stops, conduction of the action potential in an affected axon, because it allows electrical current to leak out of the axonal membrane. Thus, demyelinating diseases have devastating effects on neuronal circuits in the brain, spinal cord, and peripheral nervous system.

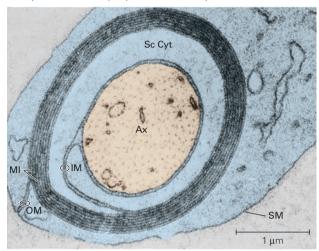

Astrocytes Support Synaptic Signaling

Astrocytes are star-shaped glia found in all areas of the brain; indeed, they constitute nearly half the number of brain cells. They play important roles in nourishing

B Myelination in the peripheral nervous system

C Development of myelin sheath in the peripheral nervous system

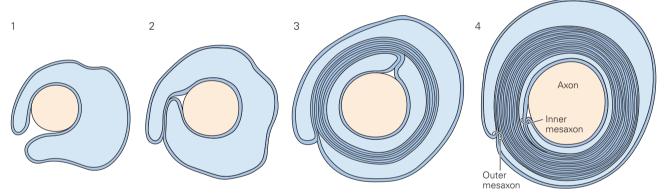

Figure 4–13 Myelin insulates the axons of both central and peripheral neurons.

A. Axons in the central nervous system are wrapped in several layers of myelin produced by oligodendrocytes. Each oligodendrocyte can myelinate many axons. (Reproduced, with permission, from Raine 1984.)

B. This electron micrograph of a transverse section through an axon (Ax) in the sciatic nerve of a mouse shows the origin of a sheet of myelin (MI) at a structure called the inner mesaxon (IM). The sheet arises from the surface membrane (SM) of a Schwann cell, which is continuous with the outer mesaxon (OM). The Schwann cell cytoplasm (Sc Cyt) still surrounds the axon; eventually, it is squeezed out and the myelin layers

become compact. (Reproduced, with permission, from Dyck et al. 1984.)

C. A peripheral nerve fiber is myelinated by a Schwann cell in several stages. In stage 1 the Schwann cell surrounds the axon. In stage 2 the outer aspects of the plasma membrane have become tightly apposed in one area. This membrane fusion reflects early myelin membrane formation. In stage 3 several layers of myelin have formed because of continued rotation of the Schwann cell cytoplasm around the axon. In stage 4 a mature myelin sheath has formed; much of the Schwann cell cytoplasm has been squeezed out of the innermost loop. (Adapted, with permission, from Williams et al. 1989.)

neurons and in regulating the concentrations of ions and neurotransmitters in the extracellular space. But astrocytes and neurons also communicate with each other to modulate synaptic signaling in ways that are still poorly understood.

Astrocytes have large numbers of thin processes that enfold all the blood vessels of the brain, and

ensheath synapses or groups of synapses. By their intimate physical association with synapses, often closer than 1 μ m, astrocytes are positioned to regulate extracellular concentrations of ions, neurotransmitters, and other molecules (Figure 4–17).

How do astrocytes regulate axonal conduction and synaptic activity? The first recognized physiological

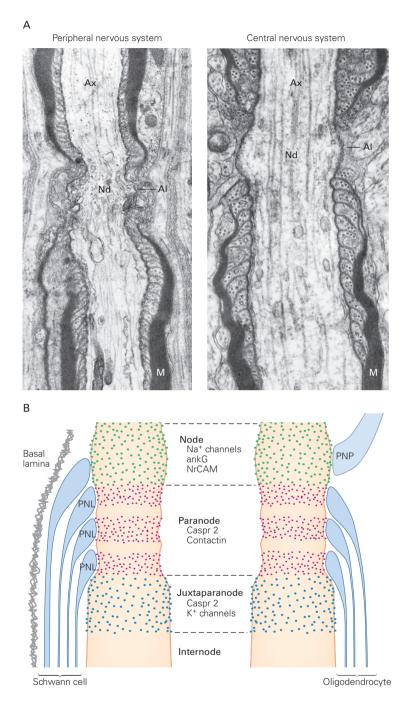

Figure 4–14 The myelin sheath of axons has regular gaps called the *nodes of Ranvier*.

A. Electron micrographs show the region of nodes in axons from the peripheral nervous system and spinal cord. The axon (Ax) runs vertically in both micrographs. The layers of myelin (M) are absent at the nodes (Nd), where the axon's membrane (axolemma, Al) is exposed. (Reproduced, with permission, from Peters et al. 1991.)

B. Regions on both sides of a node of Ranvier are rich in stable contacts between myelinating cells and the axon, to ensure that the nodes do not move or change in size and to restrict the localization of K^+ and Na^+ channels in the axon. Potassium permeable

channels and the adhesion protein Caspr2 are concentrated in the juxtaparanode. Paranodal loops (PNL) of Schwann cell or oligodendrocyte cytoplasm form a series of stable junctions with the axon. The paranode region is rich with adhesion proteins such as Caspr2, contactin, and neurofascin (NF155). At the nodes in central axons, perinodal astroglial processes (PNP) contact the axonal membrane, which is enormously rich with Na⁺ channels. This localization of Na⁺ permeability is a major basis for the saltatory conduction in myelinated axons. The membrane-cytoskeletal linker ankyrin G (ankG) and the cell adhesion molecules NrCAM and NF186 are also concentrated at the nodes. (Reproduced, with permission, from Peles and Salzer 2000.)

Box 4-3 Defects in Myelin Proteins Disrupt Conduction of Nerve Signals

Because in myelinated axons normal conduction of the nerve impulse depends on the insulating properties of the myelin sheath defective myelin can result in severe disturbances of motor and sensory function.

Many diseases that affect myelin, including some animal models of demyelinating disease, have a genetic basis. The *shiverer* (or *shi*) mutant mice have tremors and frequent convulsions and tend to die young. In these mice the myelination of axons in the central nervous system is greatly deficient and the myelination that does occur is abnormal.

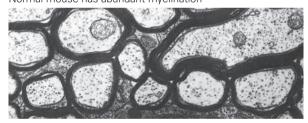

The mutation that causes this disease is a deletion of five of the six exons of the gene for myelin basic protein, which in the mouse is located on chromosome 18. The mutation is recessive; a mouse develops the disease only if it has inherited the defective gene from both parents. *Shiverer* mice that inherit both defective genes have only approximately 10% of the myelin basic protein found in normal mice.

When the wild-type gene is injected into fertilized eggs of the *shiverer* mutant with the aim of rescuing the mutant, the resulting transgenic mice express the wild-type gene but produce only 20% of the normal amounts of MBPs. Nevertheless, myelination of central neurons in the transgenic mice is much improved. Although they still have occasional tremors, the transgenic mice do not have convulsions and have a normal life span (Figure 4–15).

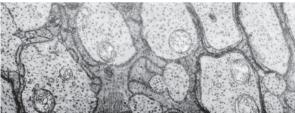

In both the central and peripheral nervous systems myelin contains a protein termed myelin-associated glycoprotein (MAG). MAG belongs to the immunoglobulin superfamily that includes several important cell surface proteins thought to be involved in cell-to-cell recognition, eg, the major histocompatibility complex of antigens, T-cell surface antigens, and the neural cell adhesion molecule (NCAM).

MAG is expressed by Schwann cells early during production of myelin and eventually becomes a component

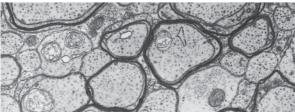

A Normal mouse has abundant myelination

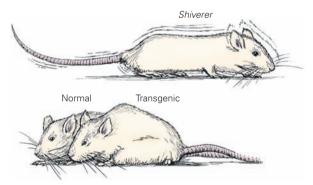

Shiverer mutant has scant myelination

Transfected normal gene improves myelination

В

Figures 4–15 A genetic disorder of myelination in mice can be partially cured by transfection of the normal gene that encodes myelin basic protein.

A. Electron micrographs show the state of myelination in the optic nerve of a normal mouse, a *shiverer* mutant, and a mutant transfected with the gene for myelin basic protein

B. The *shiverer* mutant exhibits poor posture and weakness. Injection of the wild-type gene into the fertilized egg of the mutant improves myelination; the treated mutant looks as perky as a normal mouse. (Reproduced, with permission, from Readhead et al. 1987.)

(continued)

Box 4–3 Defects in Myelin Proteins Disrupt Conduction of Nerve Signals (continued)

of mature (compact) myelin. Its early expression, subcellular location, and structural similarity to other surface recognition proteins suggest that it is an adhesion molecule important for the initiation of the myelination process. Two isoforms of MAG are produced from a single gene through alternative RNA splicing.

More than half of the protein in myelin in central axons is the proteolipid protein (PLP), which has five membrane-spanning domains. Proteolipids differ from lipoproteins in that they are insoluble in water. Proteolipids are soluble only in organic solvents because they contain long chains of fatty acids that are covalently linked to amino acid residues throughout the proteolipid molecule. In contrast, lipoproteins are noncovalent complexes of proteins with lipids and often serve as soluble carriers of the lipid moiety in the blood.

Many mutations of PLP are known in humans as well as in other mammals, eg, the *jimpy* mouse. One example is Pelizaeus-Merzbacher disease, a heterogeneous X-linked disease in humans. Almost all PLP mutations occur in a membrane-spanning domain of the molecule. Mutant animals have reduced amounts of (mutated) PLP, hypomyelination, and degeneration and death of oligodendrocytes. These observations suggest that PLP is involved in the compaction of myelin.

The major protein in mature peripheral myelin, myelin protein zero (MPZ or P_0), spans the plasmalemma of the Schwann cell. It has a basic intracellular domain and, like MAG, is a member of the immunoglobulin

superfamily. The glycosylated extracellular part of the protein, which contains the immunoglobulin domain, functions as a homophilic adhesion protein during myelin ensheathing by interacting with identical domains on the surface of the apposed membrane. Genetically engineered mice in which the function of P_0 has been eliminated have poor motor coordination, tremors, and occasional convulsions.

Observation of *trembler* mouse mutants led to the identification of peripheral myelin protein 22 (PMP22). This Schwann cell protein spans the membrane four times and is normally present in compact myelin. PMP22 is altered by a single amino acid in the mutants. A similar protein is found in humans, encoded by a gene on chromosome 17.

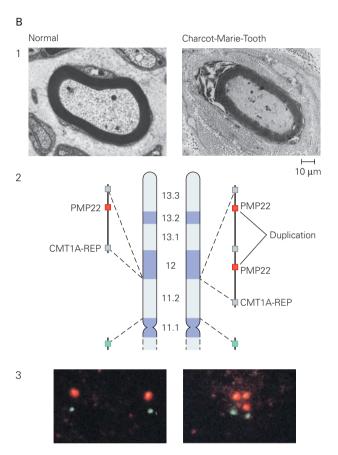

Mutations of the PMP22 gene on chromosome 17 produce several hereditary peripheral neuropathies, while a duplication of this gene causes one form of Charcot-Marie-Tooth disease (Figure 4–16). Charcot-Marie-Tooth disease, the most common inherited peripheral neuropathy, and is characterized by progressive muscle weakness, greatly decreased conduction in peripheral nerves, and cycles of demyelination and remyelination. Because both duplicated genes are active, the disease results from *increased* production of PMP22 (a two- to three-fold increase in gene dosage). Mutations in a number of genes expressed by Schwann cells can produce inherited peripheral neuropathies.

Figure 4–16 Charcot-Marie-Tooth disease (type 1A) results from increased production of peripheral myelin protein 22.

A. A patient with Charcot-Marie-Tooth disease shows impaired gait and deformities. (Reproduced, with permission, from Charcot's original description of the disease, Charcot and Marie 1886.)

- **B.** The disordered myelination in Charcot-Marie-Tooth disease (type 1A) results from increased production of peripheral myelin protein 22 (PMP22).
- 1. Sural nerve biopsies from a normal individual (Reproduced, with permission, from A. P. Hays) and from a patient with Charcot-Marie-Tooth disease. (Reproduced, with permission, from Lupski and Garcia 1992.) In the patient's biopsy the myelin sheath is slightly thinner than normal and is surrounded by concentric rings of Schwann cell processes. These changes are typical of the recurrent demyelination and remyelination seen in this disorder.
- 2. The increase in PMP22 is caused by a duplication of a normal 1.5 megabase region of the DNA on the short arm of chromosome 17 at 17p11.2-p12. The PMP22 gene is flanked by two similar repeat sequences (CMT1A-REP), as shown in the normal chromosome 17 on the left. Normal individuals have two normal chromosomes. In patients with the disease (right) the duplication results in two functioning PMP22 genes, each flanked by a repeat sequence. The normal and duplicated regions are shown in the expanded diagrams indicated by the dashed lines. (The repeats are thought to have given rise to the original
- duplication, which was then inherited. The presence of two similar flanking sequences with homology to a transposable element is believed to increase the frequency of unequal crossing-over in this region of chromosome 17 because the repeats enhance the probability of mispairing of the two parental chromosomes in a fertilized egg.)
- 3. Although a large duplication (3 megabases) cannot be detected in routine examination of chromosomes in the light microscope, evidence for the duplication can be obtained using fluorescence in situ hybridization. The PMP22 gene is detected with an oligonucleotide probe tagged with the dye Texas Red. An oligonucleotide probe that hybridizes with DNA from region 11.2 (indicated by the green segment close to the centromere), is used for in situ hybridization on the same sample. A nucleus from a normal individual (left) shows a pair of chromosomes, each with one red site (PMP22 gene) for each green site. A nucleus from a patient with the disease (right) has one extra red site, indicating that one chromosome has one PMP22 gene and the other has two PMP22 genes. (Adapted, with permission, from Garcia et al. 1991)

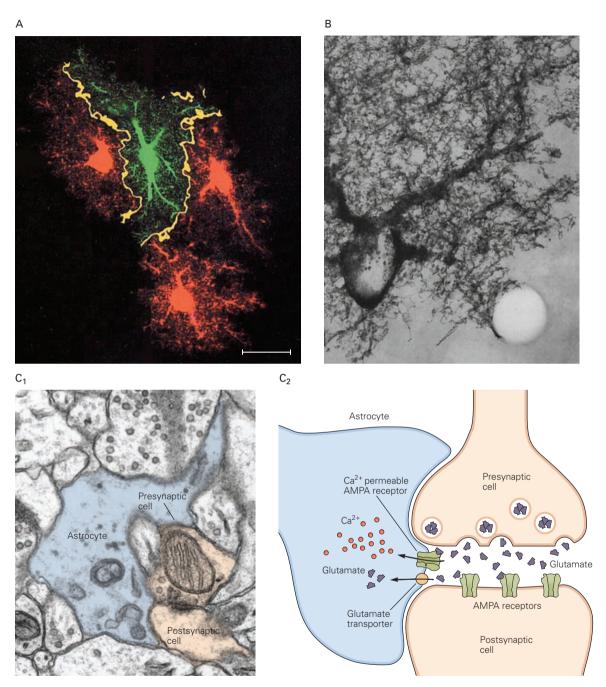

Figure 4–17 Astrocyte processes are intimately associated with synapses.

A. Each of four adjacent astrocytes appears to occupy a distinct volume, with only a small overlap at the ends of their processes. In this overlap area astrocytes are connected to each other by gap junctions. Bar = 20 μm . (Reproduced, with permission, from Bushong et al. 2002.)

B. This high-voltage electron micrograph shows several thick processes emanating from the cell body of an astrocyte and branching into extraordinarily fine processes. The typical astrocyte envelopment of a blood vessel is shown at lower right. (Reproduced, with permission, from Hama, Ari, and Kosaka 1994.)

C. The processes of astrocytes are intimately associated with both presynaptic and postsynaptic elements. 1. The close association between astrocyte processes and synapses is seen in this electron micrograph of hippocampal cells. (Reproduced, with permission, from Ventura and Harris 1999.) 2. Glutamate released from the presynaptic neuron activates not only receptors on the postsynaptic neuron but also α -amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) receptors on astrocytes. Astrocytes remove glutamate from the synaptic cleft by uptake through high-affinity transporters. (Reproduced, with permission, from Gallo and Chittajallu 2001.)

role was that of K^+ buffering. When neurons fire action potentials they release K^+ ions into the extracellular space. Because astrocytes have high concentrations of K^+ channels in their membranes, they can act as *spatial buffers*: They take up K^+ at sites of neuronal activity, mainly synapses, and release it at distant contacts with blood vessels. Astrocytes can also accumulate K^+ locally within their cytoplasmic processes along with Cl^- ions and water. Unfortunately, accumulation of ions and water in astrocytes can contribute to severe brain swelling after head injury.

Astrocytes also regulate neurotransmitter concentrations in the brain. For example, high-affinity transporters located in the astrocyte's plasma membrane rapidly clear the neurotransmitter glutamate from the synaptic cleft (Figure 4–17C). Once within the glial cell, glutamate is converted to glutamine by the enzyme glutamine synthetase. Glutamine is then transferred to neurons, where it serves as an immediate precursor of glutamate (see Chapter 13). Interference with these uptake mechanisms results in high concentrations of extracellular glutamate that can lead to the death of neurons, a process termed excitotoxicity. Astrocytes also degrade dopamine, norepinephrine, epinephrine, and serotonin.

Astrocytes sense when neurons are active because they are depolarized by the K+ released by neurons and have neurotransmitter receptors similar to those of neurons. For example, Bergmann glia in the cerebellum express glutamate receptors. Thus, the glutamate released at cerebellar synapses affects not only postsynaptic neurons but also astrocytes near the synapse. The binding of these ligands to glial receptors increases the intracellular free Ca²⁺ concentration, which has several important consequences. The processes of one astrocyte connect to those of neighboring astrocytes through gap junctions, allowing transfer of ions and small molecules between many cells. An increase in free Ca²⁺ within one astrocyte increases Ca²⁺ concentrations in adjacent astrocytes. This spread of Ca²⁺ through the astrocyte network occurs over hundreds of micrometers. It is likely that this Ca²⁺ wave modulates nearby neuronal activity by triggering the release of nutrients and regulating blood flow. An increase in Ca²⁺ in astrocytes leads to the secretion of signals that enhance synaptic function, but the specific molecular components of these signals are not understood.

Astrocytes also are important for the development of synapses. They prepare the surface of the neuron for synapse formation and stabilize newly formed synapses. For example, astrocytes secrete substances called thrombospondins that promote the formation of new synapses. In pathological states, such as

chromatolysis produced by axonal damage, astrocytes and presynaptic terminals temporarily retract from the damaged postsynaptic cell bodies. Astrocytes release neurotrophic and gliotrophic factors that promote the development and survival of neurons and oligodendrocytes. Astrocytes also protect other cells from the effects of oxidative stress. For example, the glutathione peroxidase in astrocytes detoxifies toxic oxygen free radicals released during hypoxia, inflammation, and neuronal degeneration.

Finally, astrocytes ensheath small arterioles and capillaries throughout the brain, forming contacts between the ends of astrocyte processes and the basal lamina around endothelial cells. The central nervous system is sequestered from the general circulation so that macromolecules in the blood do not passively enter the brain and spinal cord (the "blood-brain barrier"). The barrier is largely the result of tight junctions between endothelial cells and cerebral capillaries, a feature not shared by capillaries in other parts of the body (see Appendix D). Nevertheless, endothelial cells have a number of transport properties that allow some molecules to pass through them into the nervous system. Because of the intimate astrocyte-blood vessel contacts, the transported molecules, such as glucose, come into contact with and can be taken up by astrocyte end-feet.

Choroid Plexus and Ependymal Cells Produce Cerebrospinal Fluid

Cells of the ependyma and choroid plexus are derived from immature neuroepithelium. The ependyma, a single layer of ciliated cuboidal cells, lines all the ventricles of the brain, helping to move cerebrospinal fluid through the ventricular system (Figure 4–18A). At several places in the lateral and fourth ventricles the ependyma is continuous with cells of the choroid plexus, which covers thin blood vessels that project into the ventricles (Figure 4–18B). These choroid plexus epithelial cells filter plasma from the blood and secrete this ultrafiltrate as cerebrospinal fluid. Cerebrospinal fluid production and the properties of choroid plexus cells are considered in detail in Appendix D.

Microglia in the Brain Are Derived from Bone Marrow

Unlike neurons, astrocytes, and oligodendrocytes, microglia do not belong to the neuroectodermal lineage. Instead they derive from bone marrow. Entering the central nervous system early in development,

A Ependyma B Choroid plexus

Figure 4-18 Ependyma and choroid plexus.

A. The ependyma is a single layer of ciliated, cuboidal cells lining the cerebral ventricles (V). High magnification of the ependymal lining (rectangle in upper image) shows the cilia on the ventricular side of the ependymal cells.

B. The choroid plexus is continuous with the ependyma but projects into the ventricles, where it covers thin blood

vessels and forms a highly-branched, papillary structure. This is the site of cerebrospinal fluid formation. High magnification shows the blood vessel core (BV) and overlying choroid plexus (CP). The arrow denotes the direction of fluid flow from capillary into ventricle during the formation of cerebrospinal fluid.

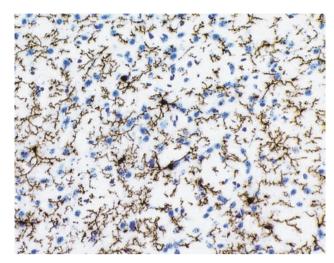

they reside in all regions of the brain throughout life (Figure 4–19). Their functions are not well understood, although they probably play an important role in immunological surveillance in the CNS, poised to react to foreign invaders.

Of all of the cells in the central nervous system, microglia are the best at processing and presenting antigens to lymphocytes and secreting cytokines and chemokines during inflammation. Thus they serve to bring lymphocytes, neutrophils, and monocytes into the central nervous system and expand the lymphocyte population, important immunological activities in infection, stroke, and immune-mediated demyelinating disease. Microglia can also become macrophages, clearing debris after infarcts (strokes) or other degenerative neurological disorders.

An Overall View

The morphology of neurons is elegantly suited to receive, conduct, and transmit signals. Dendrites provide a highly branched, elongated surface for receiving signals. Axons conduct electrical impulses rapidly over long distances to their synaptic terminals, which release neurotransmitters onto target cells. Although all neurons conform to the same basic cell plan, different types of neurons vary widely in their specific morphological features.

Neurons in different locations differ in the complexity of their dendritic trees, extent of axon branching, as well as in the number of synaptic terminals that they form and receive. The functional significance of these morphological differences is plainly evident. For example,

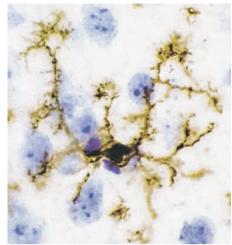

Figure 4–19 Large numbers of microglia reside in the mammalian central nervous system. The micrograph on the left shows microglia in the cerebral cortex of an adult mouse (in brown, immunocytochemistry). The blue spots are

the nuclei of nonmicroglial cells. The microglial cells have fine, lacy processes, as shown in the higher magnification micrograph on the right. (Reproduced, with permission, from Berry et al. 2002.)

motor neurons must have a more complex dendritic tree than sensory neurons, as even simple reflex activity requires integration of many excitatory and inhibitory inputs. As we shall see in subsequent chapters, different types of neurons have different neurotransmitters, ion channels, and neurotransmitter receptors. Together, these biochemical, morphological, and electrophysiological differences contribute to the great complexity of information processing in the brain.

Most neuronal proteins are synthesized in the cell body, but some synthesis occurs in dendrites and axons. The newly synthesized proteins are folded with the assistance of chaperones, and their final structure is often modified by permanent or reversible post-translational modifications. The final destination of a protein in the neuron depends on signals encoded in its amino acid sequence. Transport of proteins and RNA occurs with great specificity and results in the vectorial transport of selected membrane components. The cytoskeleton provides an important framework for the transport of organelles to different intracellular locations in addition to controlling neuronal shape.

As we shall see in later chapters, all these fundamental cell-biological processes are profoundly controlled by electrical activity, which produces the dramatic changes in cell structure and function by which neural circuits adapt to experience (learning).

Finally, the nervous system also contains several types of glial cells. Oligodendrocytes and Schwann cells produce the myelin insulation that enables axons to

conduct electrical signals rapidly. Astrocytes ensheath other parts of the neuron, particularly synapses. Glia control extracellular ion and neurotransmitter concentrations, and actively participate in the formation and function of synapses.

An Overall View

SIGNALING IN THE BRAIN DEPENDS on the ability of nerve cells to respond to very small stimuli with rapid and large changes in the electrical potential difference across the cell membrane. In sensory cells, the membrane potential changes in response to minute physical stimuli: Receptors in the eye respond to a single photon of light; olfactory neurons detect a single molecule of odorant; and hair cells in the inner ear respond to tiny movements of atomic dimensions. These sensory responses ultimately lead to the firing of

an action potential during which the membrane potential changes up to 500 volts per second.

The rapid changes in membrane potential that underlie signaling throughout the nervous system are mediated by ion channels, a class of integral membrane proteins found in all cells of the body. The ion channels of nerve cells are optimally tuned to respond to specific physical and chemical signals. They are also heterogeneous—in different parts of the nervous system different types of channels carry out specific signaling tasks.

Because of their key roles in electrical signaling, malfunctioning of ion channels can cause a wide variety of neurological diseases (see Chapter 14). Diseases caused by ion channel malfunction are not limited to the brain; cystic fibrosis, skeletal muscle disease, and certain types of cardiac arrhythmia, for example, are also caused by ion channel malfunction. Moreover, ion channels are often the site of action of drugs, poisons, or toxins. Thus ion channels have crucial roles in both the normal physiology and pathophysiology of the nervous system.

In addition to ion channels, nerve cells contain a second important class of proteins specialized for moving ions across cell membranes, the ion transporters or pumps. These proteins do not participate in rapid neuronal signaling but rather are important for establishing and maintaining the concentration gradients of physiologically important ions between the inside and outside of the cell. As we will see in this chapter and Chapter 6, ion transporters differ in important aspects from ion channels, but also share certain common features.

Rapid Signaling in the Nervous System Depends on Ion Channels

Ion channels have three important properties: (1) They recognize and select specific ions, (2) they open and close in response to specific electrical, mechanical, or chemical signals, and (3) they conduct ions across the membrane. The channels in nerve and muscle conduct ions across the cell membrane at extremely rapid rates, thereby providing a large flow of electric charge. Up to 100 million ions can pass through a single channel each second. This current causes the rapid changes in membrane potential required for signaling, as will be discussed in Chapter 7. The fast flow of ions through channels is comparable to the turnover rate of the fastest enzymes, catalase and carbonic anhydrase, which are limited by diffusion of substrate. (The turnover rates of most other enzymes are considerably slower, ranging from 10 to 1,000 per second.)

In light of such an extraordinary rate of ion flow, channels are surprisingly selective for the ions they allow to permeate. Each type of channel allows only one or a few types of ions to pass. For example, the negative resting potential of nerve cells is largely determined by a class of K⁺ channels that are 100-fold more permeable to K⁺ than to Na⁺. In contrast, during the action potential a class of Na⁺ channels is activated that are 10- to 20-fold more permeable to Na⁺ than to K⁺. Thus a key to the great versatility of neuronal signaling is the regulated activation of different classes of ion channels, each of which is selective for specific ions.

Many channels open and close in response to a specific event: Voltage-gated channels are regulated by changes in membrane potential, ligand-gated channels by chemical transmitters, and mechanically gated channels by pressure or stretch. However, some channels are normally open in the cell at rest. The ion flux through these "resting" channels contributes significantly to the resting potential.

Ion channels are limited to catalyzing the passive movement of ions down their thermodynamic concentration and electrical gradients. For example, Na⁺ ions enter a cell through voltage-gated Na⁺ channels during an action potential because the external Na⁺ concentration is much greater than the internal concentration; the open channels allow Na⁺ to diffuse into the cell down its concentration gradient. With such passive ion movement the Na⁺ concentration gradient would eventually dissipate were it not for ion pumps. Different types of ion pumps maintain the concentration gradients for Na⁺, K⁺, Ca²⁺, Cl⁻, and other ions.

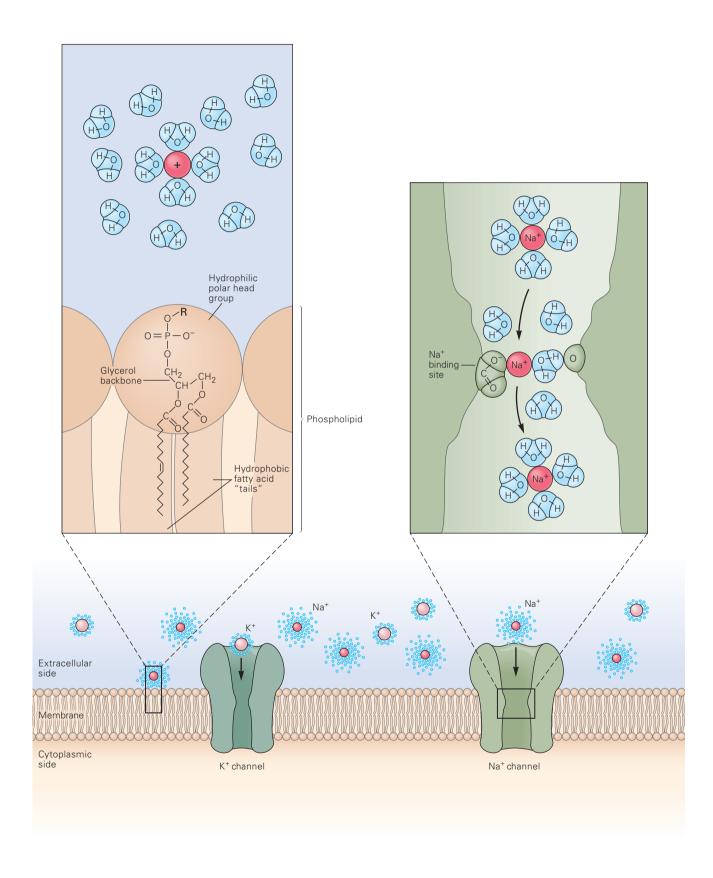

These pumps differ from ion channels in two important details. First, whereas open ion channels have a continuous water-filled pathway through which ions flow unimpeded from one side of the membrane to the other, each time a pump moves an ion, or a group of a few ions, across the membrane, it must undergo a series of conformational changes. As a result, the rate of ion flow through pumps is 100 to 100,000 times slower than through channels. Second, pumps that maintain ion gradients use energy, often in the form of adenosine triphosphate (ATP), to transport ions against their electrical and chemical gradients. Such ion movements are termed *active transport*. The function and structure of ion pumps is considered in detail at the end of this chapter and in Chapter 6.

In this chapter we examine four questions: Why do nerve cells have channels? How can channels conduct ions at such high rates and still be selective? How are channels gated? How are the properties of these channels modified by various intrinsic and extrinsic conditions? In addition, we compare the molecular structure of various channels and consider how channel structure explains function. Finally, we compare ion movements through channels and transporters. In succeeding chapters we consider how resting channels and pumps generate the resting potential (Chapter 6), how voltage-gated channels generate the action potential (Chapter 7), and how ligand-gated channels produce synaptic potentials (Chapters 8, 9, and 10).

Ion Channels Are Proteins That Span the Cell Membrane

To appreciate why nerve cells use channels, we need to understand the nature of the plasma membrane and the physical chemistry of ions in solution. The plasma membrane of all cells, including nerve cells, is approximately 6 to 8 nm thick and consists of a mosaic of lipids and proteins. The core of the membrane is formed by a double layer of phospholipids. Embedded within this continuous lipid sheet are integral membrane proteins, including ion channels.

The lipids of the membrane do not mix with water—they are hydrophobic. In contrast, the ions within the cell and those outside strongly attract water molecules—they are hydrophilic (Figure 5–1). Ions attract water because water molecules are dipolar: Although the net charge on a water molecule is zero, charge is separated within the molecule. The oxygen atom in a water molecule tends to attract electrons and so bears a small net negative charge, whereas the

hydrogen atoms tend to lose electrons and therefore carry a small net positive charge. As a result of this unequal distribution of charge, positively charged ions (cations) are strongly attracted electrostatically to the oxygen atom of water, and negatively charged ions (anions) are attracted to the hydrogen atoms. Similarly, ions attract water; in fact they become surrounded by electrostatically bound *waters of hydration* (see Figure 5–1).

An ion cannot move away from water into the noncharged hydrocarbon tails of the lipid bilayer in the membrane unless a large amount of energy is expended to overcome the attraction between the ion and the surrounding water molecules. For this reason it is extremely unlikely that an ion will move from solution into the lipid bilayer, and therefore the bilayer itself is almost completely impermeable to ions. Rather, ions cross the membrane through ion channels, specialized pores or openings in the membrane where, as we shall see, the energetics favor ion movement.

Ion channels are not simply holes in the lipid membrane but are distinct protein structures that span the lipid bilayer. Although their molecular nature has been known with certainty for only approximately 25 years, the idea of ion channels dates to the work of Ernst Brücke at the end of the 19th century. Physiologists had long known that, despite the fact that the cell membrane acts as a barrier, cell membranes are nevertheless permeable to water and many small solutes, including some ions. To explain osmosis, the flow of water across biological membranes, Brücke proposed that membranes contained channels or pores that allow water but not larger solutes to flow. Over 100 years later Peter Agre

found that a family of proteins termed aquaporins form channels with a high selective permeability to water. At the beginning of the 20th century William Bayliss suggested that water-filled channels would permit ions to cross the cell membrane easily, as the ions would not need to be stripped of their waters of hydration.

The idea that ions move through channels leads to a question: How can a water-filled channel conduct ions at high rates and yet be selective? How, for instance, does a channel allow K⁺ ions to pass while excluding Na⁺ ions? Selectivity cannot be based solely on the diameter of the ion because K⁺, with a crystal radius of 0.133 nm, is larger than Na⁺ (crystal radius of 0.095 nm). Because ions in solution are surrounded by waters of hydration, the ease with which an ion moves in solution (its mobility or diffusion constant) depends on the size of the ion together with the shell of water surrounding it.

The smaller an ion, the more highly localized is its charge and the stronger its electric field. As a result, smaller ions attract water more strongly. Thus, as Na⁺ moves through solution its stronger electrostatic attraction for water causes it to have a larger water shell, which tends to slow it down relative to K⁺. Because of its larger water shell, Na⁺ behaves as if it is larger than K⁺. In fact, there is a precise relationship between the size of an ion and its mobility in solution: the smaller the ion, the lower its mobility. We therefore can construct a model of a channel that selects K⁺ rather than Na⁺ simply on the basis of the interaction of the two ions with water in a water-filled channel (Figure 5–1).

Although this model explains how a channel can select K⁺ and exclude Na⁺, it does not explain how a

Figure 5–1 (Opposite) The permeability of the cell membrane to ions is determined by the interaction of ions with water, the membrane lipid bilayer, and ion channels. lons in solution are surrounded by a cloud of water molecules (waters of hydration) that are attracted by the net charge of the ion. This cloud is carried along by the ion as it diffuses through solution, increasing the effective size of the ion. It is energetically unfavorable, and therefore improbable, for the ion to leave this polar environment to enter the nonpolar environment of the lipid bilayer formed from phospholipids. Phospholipids have a hydrophilic head and a hydrophobic tail. The hydrophobic tails join to exclude water and ions, whereas the polar hydrophilic heads face the aqueous environments of the extracellular fluid and cytoplasm. The phospholipid is composed of a backbone of glycerol in which two -OH groups are linked by ester bonds to fatty acid molecules. The third -OH group of glycerol is linked to phosphoric acid. The phosphate group is further linked to one of a variety of small, polar alcohol head groups (R).

lon channels are integral membrane proteins that span the lipid bilayer, providing a pathway for ions to cross the membrane. The channels are selective for specific ions. Potassium channels have a narrow pore that excludes Na^+ . Although a Na^+ ion is smaller than a K^+ ion, in solution the effective diameter of Na^+ is larger because its local field strength is more intense, causing it to attract a larger cloud of water molecules. The K^+ channel pore is too narrow for the hydrated Na^+ ion to permeate.

Sodium channels have a selectivity filter that weakly binds Na⁺ ions. According to the hypothesis developed by Bertil Hille and colleagues, a Na⁺ ion binds transiently at an active site as it moves through the filter. At the binding site the positive charge of the ion is stabilized by a negatively charged amino acid residue on the channel wall and also by a water molecule that is attracted to a second polar amino acid residue on the other side of the channel wall. It is thought that a K⁺ ion, because of its larger diameter, cannot be stabilized as effectively by the negative charge and therefore will be excluded from the filter. (Modified, with permission, from Hille 1984.)

channel could select Na^+ and exclude K^+ . Moreover, the model cannot account quantitatively for the very high ionic selectivity exhibited by biological K^+ channels. This problem led many physiologists in the 1930s and 1940s to abandon the channel theory in favor of the idea that ions cross cell membranes by first binding to a specific carrier protein, which then shuttles the ion through the membrane. In this carrier model selectivity is based on the chemical binding between the ion and the carrier protein, not on the mobility of the ion in solution.

Even though we now know that ions can cross membranes by means of a variety of transport macromolecules, the Na⁺-K⁺ pump being a well-characterized example (Chapter 6), many properties of membrane ion conductances do not fit the carrier model. Most important is the rapid rate of ion transfer across membranes. This transfer rate was first examined in the early 1970s by measuring the transmembrane current initiated when the neurotransmitter acetylcholine (ACh) binds its receptor in the cell membrane of skeletal muscle fibers at the synapse between nerve and muscle. Using measurements of membrane current noise, small statistical fluctuations in the mean ionic current induced by ACh, Bernard Katz and Ricardo Miledi concluded that the current conducted by a single ACh receptor is 10 million ions per second. In contrast, the Na⁺-K⁺ pump transports at most 100 ions per second.

If the ACh receptor acted as a carrier, it would have to shuttle an ion across the membrane in $0.1~\mu s$ (one ten-millionth of a second), an implausibly fast rate. The 100,000-fold difference in rates strongly suggests that the ACh receptor (and other ligand-gated receptors) must conduct ions through a channel. Later measurements in many voltage-gated pathways selective for K^+ , Na^+ , and Ca^{2+} also demonstrated large currents carried by single macromolecules, indicating that they too are channels.

But we are still left with the problem of what makes a channel selective. To explain selectivity, Bertil Hille extended the pore theory by proposing that channels have narrow regions that act as molecular sieves. At this selectivity filter an ion must shed most of its waters of hydration to traverse the channel; in their place weak chemical bonds (electrostatic interactions) form with polar (charged) amino acid residues that line the walls of the channel (Figure 5-1). Because shedding its waters of hydration is energetically unfavorable, the ion will traverse a channel only if its energy of interaction with the selectivity filter compensates for the loss of the energy of interaction with its waters of hydration. Ions traversing the channel are normally bound to the selectivity filter for only a short time (less than 1 µs), after which electrostatic and diffusional forces

propel the ion through the channel. In channels where the pore diameter is large enough to accommodate several water molecules, an ion need not be stripped completely of its water shell.

How is this chemical recognition and specificity established? One theory was developed in the early 1960s by George Eisenman to explain the properties of ion-selective glass electrodes (which are similar to pH electrodes but select among the alkali metal cations). According to this theory, a binding site with a high negative field strength—for example, one formed by negatively charged carboxylic acid groups of glutamate or aspartate—will bind Na⁺ more tightly than K⁺. This selectivity results because the electrostatic interaction between two charged groups, as governed by Coulomb's law, depends inversely on the distance between the two groups.

Because Na⁺ has a smaller crystal radius than K⁺, it will approach a negative site more closely than K⁺ and thus will derive a more favorable free-energy change on binding. This compensates for the requirement that Na⁺ lose some of its waters of hydration to traverse the narrow selectivity filter. In contrast, a binding site with a low negative strength—one that is composed, for example, of polar carbonyl or hydroxyl oxygen atoms—would select K⁺ over Na⁺. At such a site the binding of Na⁺ would not provide a sufficient free-energy change to compensate for the loss of the ion's waters of hydration, which Na⁺ holds strongly. However, such a site would be able to compensate for the loss of a K⁺ ion's associated water molecules as the larger K⁺ ions interact more weakly with water. It is currently thought that ion channels are selective both because of specific chemical interactions and because of molecular sieving based on pore diameter.

Currents Through Single Ion Channels Can Be Recorded

A complete understanding of how channels work requires three-dimensional structural information. X-ray crystallographic and other structural analyses have been informative in the study of enzymes and other soluble proteins but have only recently been applied to integral membrane proteins, such as ion channels, because their transmembrane hydrophobic regions make them difficult to crystallize. Nevertheless, for the past 35 years single-channel recording has provided important functional information that has yielded significant insights into channel structure.

Before it became possible to resolve the small amount of current that flows through a single ion channel in biological membranes, channel function was studied in artificial lipid bilayers. In the early 1960s Paul Mueller and Donald Rudin developed a technique for forming functional lipid bilayers by painting a thin drop of phospholipid over a hole in a nonconducting barrier that separates two salt solutions. Although lipid membranes are highly impermeable to ions, ionic permeability of the membrane increases dramatically when certain peptide antibiotics are added to the salt solution. Early studies with gramicidin A, a 15-amino acid cyclic peptide, were especially informative. Application of low concentrations of gramicidin A brings about small steplike changes in current across the membrane. These brief pulses of current reflect the all-or-none opening and closing of the single ion channel formed by the peptide.

The current through a single gramicidin channel varies with membrane potential in a linear manner;

that is, the channel behaves as a simple resistor (Figure 5–2). The amplitude of the single-channel current can thus be obtained from Ohm's law, i = V/R, where i is the current through the single channel, V is the voltage across the membrane, and R is the resistance of the open channel. The resistance of a single open channel is approximately 8×10^{10} ohms (Figure 5–2C). In dealing with ion channels it is more useful to speak of the reciprocal of resistance or conductance ($\gamma = 1/R$), as this provides an electrical measure related to ion permeability. Thus, Ohm's law can be expressed as $i = \gamma \times V$. The conductance of the gramicidin A channel is approximately 12×10^{-12} siemens (S), or 12 picosiemens (pS), where 1 S equals 1/ohm.

The insights into basic channel properties obtained from artificial membranes were later confirmed in biological membranes by the patch-clamp technique, developed by Erwin Neher and Bert Sakmann in 1976 (Box 5–1). A glass micropipette containing ACh—the

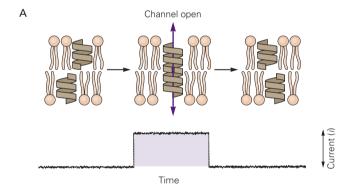

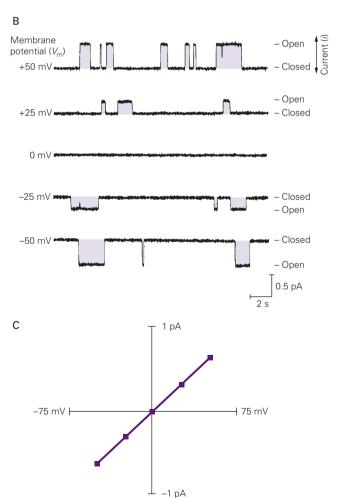

Figure 5–2 Characteristics of the current in a single ion channel. The data presented here were obtained from a channel formed by the addition of gramicidin A molecules to the solution bathing an artificial lipid bilayer.

A. A functional gramicidin A channel is thought to form by end-to-end dimerization of two gramicidin peptides. (Reproduced, with permission, from Sawyer, Koeppe, and Andersen 1989.)

- B. The channel opens and closes in an all-or-none fashion, resulting in brief current pulses through the membrane. If the electrical potential across the membrane ($V_{\rm m}$) is varied, the current through the channel (i) changes proportionally. $V_{\rm m}$ is measured in millivolts (mV); i is measured in picoamperes (pA).
- **C.** A plot of the current through the channel versus the potential difference across the membrane reveals that the current is linearly related to the voltage; in other words, the channel behaves as an electrical resistor that follows Ohm's law (i = V/R or $i = \gamma \times V$). (Data reproduced, with permission, from Olaf Andersen and Lyndon Providence.)

Box 5-1 Recording Current in Single Ion Channels: The Patch Clamp

The patch-clamp technique was developed in 1976 by Erwin Neher and Bert Sakmann to record current from single ion channels. It is a refinement of the original voltage clamp technique (see Box 7–1).

A small fire-polished glass micropipette with a tip diameter of approximately 1 μm is pressed against the membrane of a skeletal muscle fiber that has been treated with proteolytic enzymes to remove connective tissue from the muscle surface. The pipette is filled with a salt solution resembling that normally found in the extracellular fluid.

A metal electrode in contact with the electrolyte in the micropipette connects the pipette to a special electrical circuit that measures the current through channels in the membrane under the pipette tip (Figure 5–3A).

In 1980 Neher discovered that applying a small amount of suction to the patch pipette greatly increased the tightness of the seal between the pipette and the membrane. The result was a seal with extremely high resistance between the inside and the outside of the pipette. The seal lowered the electronic noise and extended the usefulness of the patch-clamp technique to the whole range of channels involved in electrical excitability, including those with small conductances.

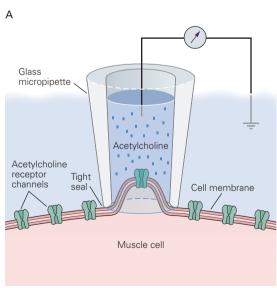

Since this discovery Neher and Sakmann, and many others, have used the patch-clamp technique to study all three major classes of ion channels—voltage-gated, ligand-gated, and mechanically gated—in a variety of neurons and other cells (Figure 5–3B).

Christopher Miller independently developed a method for incorporating channels from biological membranes into artificial lipid bilayers. Biological membranes are first homogenized in a laboratory blender; centrifugation of the homogenate then separates out a portion composed only of membrane vesicles. Under appropriate ionic conditions these membrane vesicles will fuse with a planar lipid membrane, incorporating any ion channel in the vesicle into the planar membrane.

This technique has two experimental advantages. First, it allows recording from ion channels in regions of cells that are inaccessible to patch clamp; for example, Miller has successfully studied a K⁺ channel isolated from the internal membrane of skeletal muscle (the sarcoplasmic reticulum). Second, it allows researchers to study how the composition of the membrane lipids influences channel function.

B. Patch-clamp recording of the current through a single ACh receptor channel as the channel switches between closed and open states. (Reproduced, with permission, from B. Sakmann.)

neurotransmitter that activates the ACh receptors in the membrane of skeletal muscle—was pressed tightly against a frog muscle membrane. Small unitary current pulses representing the opening and closing of a single ACh receptor channel were recorded from the area of the membrane under the pipette tip. As with gramicidin A channels, the relation between current and voltage in the ACh receptor channel is linear (Figure 5–2), with a single-channel conductance of approximately 25 pS. This generates a unitary current of 2 pA (picoamperes) at a membrane potential of –80 mV (millivolts), which corresponds to a flux of around 12.5 million ions per second.

Ion Channels in All Cells Share Several Characteristics

Most cells are capable of local signaling, but only nerve and muscle cells are specialized for rapid signaling over long distances. Although nerve and muscle cells have a particularly rich variety and high density of membrane ion channels, their channels do not differ fundamentally from those of other cells in the body. In this section we describe the general properties of ion channels found in a wide variety of cells.

The Flux of Ions Through a Channel Is Passive

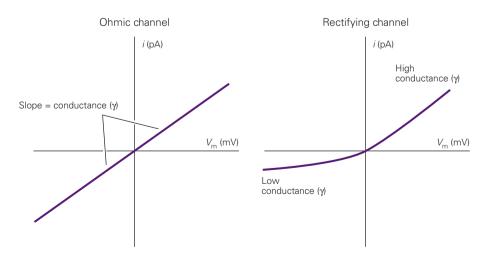

The flux of ions through ion channels is passive, requiring no expenditure of metabolic energy by the channels. The direction and eventual equilibrium for this flux are determined not by the channel itself, but rather by the electrostatic and diffusional driving forces across the membrane.

Ion channels allow particular types of ions to cross the membrane, selecting either cations or anions to permeate. Some types of cation-selective channels allow the cations that are usually present in extracellular fluid—Na $^+$, K $^+$, Ca $^{2+}$, and Mg $^{2+}$ —to pass almost indiscriminately. However, many other cation-selective channels are permeable primarily to a single type of ion, whether it is Na $^+$, K $^+$, or Ca $^{2+}$. Most types of anion-selective channels are also highly discriminating; they conduct only one physiological ion, chloride (Cl $^-$).

The kinetic properties of ion permeation are best described by the channel's conductance, which is determined by measuring the current (ion flux) through the open channel in response to an electrochemical driving force. The net electrochemical driving force is determined by two factors: the electrical potential difference across the membrane and the concentration gradients of the permeant ions across the membrane. Changing either one can change the net driving force (see Chapter 6).

As we have seen, in some open channels the current varies linearly with driving force—that is, the channels behave as simple resistors. In others the current is a nonlinear function of driving force. This type of channel behaves as a rectifier—it conducts ions more readily in one direction than in the other because of asymmetry in the channel's structure or environment. Whereas the conductance of a resistor-like channel is constant—it is the same at all voltages—the conductance of a rectifying channel is variable and must be determined by plotting current versus voltage over the entire physiological range of membrane potential (Figure 5–4).

Figure 5-4 Current-voltage relations. In many ion channels the relation between current through the open channel and membrane voltage is linear (left plot). Such channels are said to be "ohmic" because they follow Ohm's law, $i = V_m/R$ or $V_m \times \gamma$, where γ is conductance. In other channels the relation between current and membrane potential is nonlinear. This kind of channel is said to "rectify," in the sense that it conducts current more readily in one direction than the other. The right plot shows an outwardly rectifying channel where positive current is larger than the negative current for a given absolute value of voltage.

The rate of net ion flux (current) through a channel depends on the concentration of the permeant ions in the surrounding solution. At low concentrations the current increases almost linearly with concentration. At higher concentrations the current tends to reach a point at which it no longer increases. At this point the current is said to *saturate*.

This saturation effect is consistent with the idea that ion flux across the cell membrane is not strictly a function of laws of electrochemical diffusion in free solution but also involves the binding of ions to specific polar sites within the pore of the channel. A simple electrodiffusion model would predict that the ionic current should continue to increase as long as the ionic concentration also increases; that is, the more charge carriers in solution, the greater the current.

The relation between current and ionic concentration for a wide range of ion channels is well described by a simple chemical binding equation, identical to the Michaelis-Menten equation for enzymes, suggesting that a single ion binds within the channel during permeation. The ionic concentration at which current reaches half its maximum defines the dissociation constant, the concentration at which half of the channels will be occupied by a bound ion. The dissociation constant in plots of current versus concentration is typically quite high, approximately 100 mM, indicating weak binding. (In typical interactions between enzymes and substrates the dissociation constant is below 1 µM.) This weak interaction indicates that the bonds between the ion and the channel are rapidly formed and broken. In fact, an ion typically stays bound in the channel for less than 1 µs. The rapid rate at which an ion unbinds is necessary for the channel to achieve the very high conduction rates responsible for the rapid changes in membrane potential during signaling.

Some ion channels are susceptible to occlusion by certain free ions or molecules in the cytoplasm or extracellular fluid. Passage through the channel can be blocked by particles that bind either to the mouth of the aqueous pore or somewhere within the pore. If the blocker is an ionized molecule that binds to a site within the pore, it will be influenced by the membrane electric field as it enters the channel. For example, if a positively charged blocker enters the channel from outside the membrane, then making the cytoplasmic side of the membrane more negative-which, according to convention, corresponds to a more negative membrane potential (see Chapter 6)—will drive the blocker into the channel through an electrostatic attraction, increasing the block. Although blockers are often toxins or drugs that originate outside the body, some are

common ions that are normally present in the cell or its environment. Physiological blockers of certain classes of channels include Mg²⁺, Ca²⁺, Na⁺, and polyamines such as spermine.

The Opening and Closing of a Channel Involve Conformational Changes

In all ion channels so far studied the channel protein has two or more conformational states that are relatively stable. Each of these stable conformations represents a different functional state. For example, each ion channel has at least one open state and one or two closed states. The transition of a channel between these different states is called *gating*.

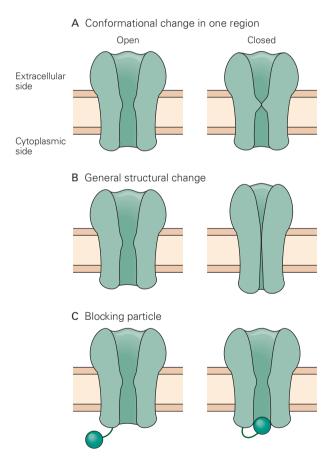

Figure 5–5 Three physical models for the opening and closing of ion channels.

A. A localized conformational change occurs in one region of the channel.

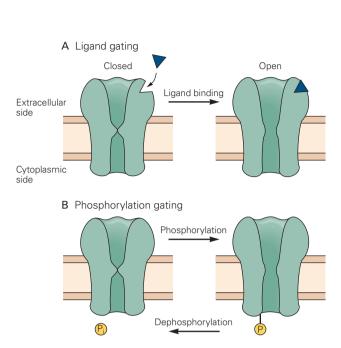

- **B.** A generalized structural change occurs along the length of the channel.
- C. A blocking particle swings into and out of the channel mouth.

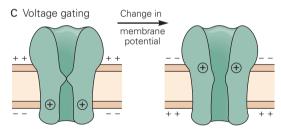

Relatively little is known about the molecular mechanisms of gating. Although the picture of a gate swinging open and shut is a convenient image, it probably is accurate only for certain cases (for example the inactivation of Na⁺ and K⁺ channels, which we describe in Chapter 7). More commonly, channel gating involves widespread changes in the channel's conformation. For example, evidence from high-resolution electron microscopy and image analysis suggests that the opening and closing of gap junction channels (which we consider in Chapter 8) involve a concerted twisting and tilting of the six subunits that make up the channel. Similar evidence indicates that ACh receptor channels open through a coordinated twisting and bending of the α -helixes of each of the five subunits that form the channel pore. In K⁺ channels movement of a ring of α -helixes that forms the internal mouth of the pore is thought to act as a gate. The molecular rearrangements that occur during the transition from closed to open states appear to enhance ion conduction through the channel not only by creating a wider lumen, but also by positioning relatively more polar amino acid constituents at the surface that lines the aqueous pore.

The primary function of ion channels in neurons is to generate transient electrical signals, and three major gating mechanisms have evolved to control channel opening (Figure 5–5). Certain channels are opened by the binding of chemical ligands, known as agonists. Some ligands bind directly to the channel either at an extracellular or intracellular site; transmitters bind at extracellular sites whereas certain cytoplasmic constituents, such as Ca2+, cyclic nucleotides and GTPbinding proteins, bind at intracellular sites. Other ligands activate cellular signaling cascades, which can covalently modify a channel through protein phosphorylation. Other ion channels are regulated by changes in membrane potential. Some voltage-gated channels act as temperature sensors; changes in temperature shift their voltage gating to higher or lower membrane potentials, giving rise to heat- or cold-sensitive channels. Finally, some channels are regulated by mechanical stretch of the membrane (Figure 5–6).

The rapid gating actions necessary for moment-tomoment signaling may also be influenced by certain long-term changes in the metabolic state of the cell. For example, the gating of some K⁺ channels is sensitive to intracellular levels of ATP. Some channel proteins contain a subunit with an integral oxidoreductase catalytic domain that is thought to alter channel gating in response to the redox state of the cell.

These regulators control the entry of a channel into one of three functional states: closed and activatable

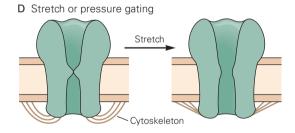

Figure 5–6 Several types of stimuli control the opening and closing of ion channels.

A. A ligand-gated channel opens when a ligand binds a receptor site on the external surface of the channel protein. The energy from ligand binding drives the channel toward an open state.

B. Some channels are regulated by protein phosphorylation and dephosphorylation. The energy for channel opening comes from the transfer of the high-energy phosphate, P_i.

C. Voltage-gated channels open and close with changes in the electrical potential difference across the membrane. The change in membrane potential causes a local conformational change by acting on a region of the channel that has a net charge.

D. Some channels open and close through stretch or pressure. The energy for gating may come from mechanical forces that are passed to the channel through the cytoskeleton.

(resting), open (active), or closed and nonactivatable (refractory). A change in the functional state of a channel requires energy. In voltage-gated channels the energy is provided by the movement of a charged region of the channel protein through the membrane's electric field. This region, the *voltage sensor*, contains a net electric charge because of the presence of basic (positively charged) or acidic (negatively charged) amino acids. The movement of the charged voltage sensor through the electric field imparts a change in free energy to the channel that alters the equilibrium between the closed and open states of the channel. For most voltage-gated channels, channel opening is favored by making the inside of the membrane more positive (depolarization).

In transmitter-gated channels gating is driven by the change in chemical-free energy that results when the transmitter binds to a receptor site on the channel protein. For mechanically activated channels the energy associated with membrane stretch is thought to be transferred to the channel either through the cytoskeleton or more directly by changes in tension of the lipid bilayer.

The stimuli that gate the channel also control the rates of transition between the open and closed states of a channel. For voltage-gated channels the rates are steeply dependent on membrane potential. Although the time scale can vary from several microseconds to a minute, the transition tends to require a few milliseconds on average. Thus, once a channel opens it stays open for a few milliseconds before closing, and after closing it stays closed for a few milliseconds before reopening. Once the transition between open and closed states begins, it proceeds virtually instantaneously (in less than 10 μs , the present limit of experimental measurements), thus giving rise to abrupt, all-or-none, step-like changes in current through the channel.

Ligand-gated and voltage-gated channels enter refractory states through different processes. Ligand-gated channels can enter the refractory state when their exposure to the agonist is prolonged. This process, called *desensitization*, is discussed in Chapter 11. The mechanisms underlying desensitization of ion channels are not yet completely understood. In some channels desensitization appears to be an intrinsic property of the interaction between ligand and channel, although in others it is a result of phosphorylation of the channel molecule by a protein kinase.

Many, but not all, voltage-gated channels enter a refractory state after opening, a process termed *inactivation*. In the inactive state the channel is closed and can no longer be opened by positive voltages. Rather, the membrane potential must be returned to its initial

negative resting level before the channel can recover from inactivation so that it can again open in response to depolarization. In voltage-gated Na⁺ and K⁺ channels inactivation is thought to result from a conformational change, controlled by a subunit or region of the channel separate from that which controls activation. In contrast, the inactivation of certain voltage-gated Ca²⁺ channels is thought to require Ca²⁺ influx. An increase in internal Ca²⁺ concentration inactivates the Ca²⁺ channel by binding to the regulatory molecule calmodulin, which is permanently associated with the Ca²⁺ channel protein (Figure 5–7).

Exogenous factors, such as drugs and toxins, can also affect the gating control sites of an ion channel. Most of these agents tend to close the channel but a few open it. Some bind to the same site at which the endogenous agonist normally binds and thereby interfere with normal gating. The binding can be weak and reversible, as in the blockade of the nicotinic AChgated channel in skeletal muscle by curare, a South American arrow poison (see Chapter 9). Or it can be strong and irreversible, as in the blockade of the same channel by the snake venom α -bungarotoxin.

Some exogenous substances act in a noncompetitive manner and affect the normal gating mechanism without directly interacting with the transmitterbinding site. For example, binding of the drug diazepam (Valium) to a regulatory site on Cl $^-$ channels that are gated by γ -aminobutyric acid (GABA), an inhibitory neurotransmitter, prolongs the opening of the channels in response to GABA (Figure 5–8). This type of indirect, allosteric effect is found in voltage- or stretch-gated channels as well.

The Structure of Ion Channels Is Inferred from Biophysical, Biochemical, and Molecular Biological Studies

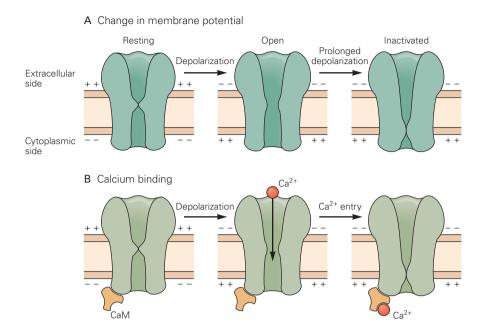

What do ion channels look like? How does the channel protein span the membrane? What happens to the structure of the channel when it opens and closes? Where along the length of the channel protein do drugs and transmitters bind?

Biochemical and molecular biological studies have provided a basic understanding of channel structure and function. All ion channels are large integral-membrane proteins with a core transmembrane domain that contains a central aqueous pore spanning the entire width of the membrane. The channel protein often contains carbohydrate groups attached to its external surface. The pore-forming region of many channels is made up of two or more subunits, which may be identical or different.

Figure 5–7 Voltage-gated channels are inactivated by two mechanisms.

A. Many voltage-gated channels enter a refractory (inactivated) state after briefly opening when the membrane is depolarized. They recover from the refractory state and return to the resting state only after the membrane potential is restored to its resting value.

B. Some voltage-dependent Ca²⁺ channels inactivate when the internal Ca²⁺ level increases following channel opening. The internal Ca²⁺ binds to calmodulin (CaM), a specific regulatory protein associated with the channel.

In addition, some channels have auxiliary subunits that modify their functional properties. These subunits may be cytoplasmic or embedded in the membrane (Figure 5–9).

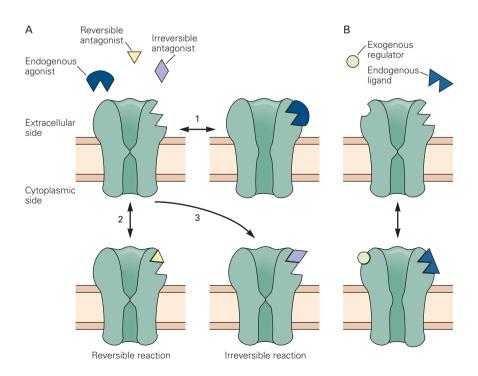

The genes for all the major classes of ion channels have been cloned and sequenced. The amino

acid sequence of a channel, inferred from its DNA sequence, can be used to create a structural model of the channel protein. Regions of secondary structure—the arrangement of the amino acid residues into α -helixes and β -sheets—as well as regions that are likely to correspond to membrane-spanning domains

Figure 5–8 Exogenous ligands, such as drugs, can bias an ion channel toward an open or closed state.

A. In channels that are normally opened by the binding of an endogenous ligand (1), a drug or toxin may block the binding of the agonist by means of a reversible (2) or irreversible (3) reaction.

B. Some exogenous agents can bias a channel toward the open state by binding to a regulatory site, distinct from the ligand-binding site that normally opens the channel.

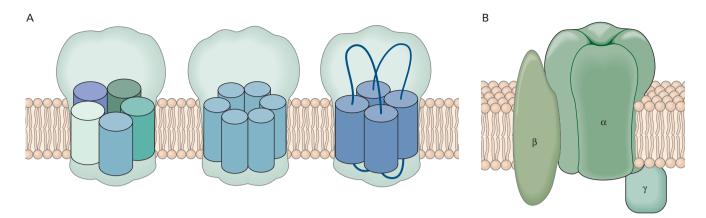

Figure 5–9 Ion channels are integral membrane proteins composed of several subunits.

A. Ion channels can be constructed as hetero-oligomers from distinct subunits (left), as homo-oligomers from a single type of subunit (middle), or from a single polypeptide chain organized

into repeating motifs, where each motif functions as the equivalent of one subunit (right).

B. In addition to one or more α -subunits that form a central pore, some channels contain auxiliary subunits (β or γ) that modulate the gating of the pore.

of the channel are predicted based on the structures of related proteins that have been experimentally determined using electron and X-ray diffraction analysis. This type of analysis identified the presence of four hydrophobic regions, each around 20 amino acids in length, in the amino acid sequence of a subunit of the ACh receptor channel. Each of these regions is thought to form an α -helix that spans the membrane (Figure 5–10).

Additional insights into channel structure and function have been obtained by comparing the amino acid sequences of the same type of channel from different species. Regions that show a high degree of similarity (that is, have been highly conserved through evolution) are likely to be important in maintaining the structure and function of the channel. Likewise, conserved regions in different but related channels are likely to serve a common biophysical function. For example, voltage-gated channels selective for different cations have a specific membrane-spanning segment that contains positively charged amino acids (lysine or arginine) spaced at every third position along an α -helix. This motif is observed in all voltage-gated cation channels, but not in transmitter-gated channels, suggesting that this charged region is important for voltage gating (see Chapter 7).

Once a structure for a channel has been proposed, it can be tested in several ways. For example, antibodies can be raised against synthetic peptides that correspond to different hydrophilic regions in the protein sequence. Immunocytochemistry can then be used to determine

whether the antibody binds to the extracellular or cytoplasmic surface of the membrane, thus defining whether a particular region of the channel is extracellular or intracellular.

The functional consequences of changes in a channel's primary amino acid sequence can be explored through a variety of techniques. One particularly versatile approach is to use genetic engineering to construct channels with parts that are derived from the genes of different species—so-called *chimeric channels*. This technique takes advantage of the fact that the same type of channel can have somewhat different properties in different species. For example, the bovine ACh receptor channel has a slightly greater single-channel conductance than the ACh receptor channel in electric fish. By comparing the properties of a chimeric channel to those of the two original channels, one can assess the functions of specific regions of the channel. This technique has been used to identify the membrane-spanning segment that forms the lining of the pore of the ACh receptor channel (see Chapter 9).

The roles of different amino acid residues or stretches of residues can be tested using site-directed mutagenesis, a type of genetic engineering in which specific amino acid residues are substituted or deleted. Finally, one can exploit the naturally occurring mutations in channel genes. A number of inherited and spontaneous mutations in the genes that encode ion channels in nerve or muscle produce changes in channel function that can underlie certain neurological

diseases. Many of these mutations are caused by localized changes in single amino acids within channel proteins, demonstrating the importance of that region for channel function.

Ion Channels Can Be Grouped into Gene Families

The great diversity of ion channels in a multicellular organism is underscored by the recent sequencing of the human genome. Our genome contains nine genes encoding variants of voltage-gated Na⁺ channels, 10 genes for different Ca⁺ channels, over 75 genes for K⁺ channels, 70 genes for ligand-gated channels, and more than a dozen genes for Cl⁻ channels. Fortunately, the evolutionary relationships between the genes that

encode ion channels provide a relatively simple framework with which to categorize them.

Most of the ion channels that have been described in nerve and muscle cells fall into a few gene superfamilies. Members of each gene superfamily have similar amino acid sequences and transmembrane topology and, importantly, related functions. Each superfamily is thought to have evolved from a common ancestral gene by gene duplication and divergence. Several superfamilies can be further classified into families of genes with more closely related structure and function.

One superfamily encodes ligand-gated ion channels that are receptors for the neurotransmitters ACh, GABA, glycine, or serotonin. All of these receptors are composed of five subunits, each of which has four

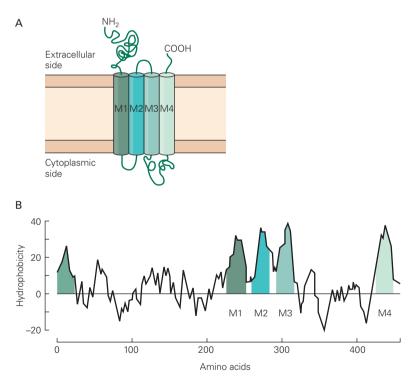

Figure 5–10 The secondary structure of membranespanning proteins.

A. A proposed secondary structure for a subunit of the nicotinic acetylcholine (ACh) receptor channel present in skeletal muscle. Each cylinder (M1–M4) represents a putative membrane-spanning α -helix comprised of approximately 20 hydrophobic amino acid residues. The membrane segments are connected by cytoplasmic or extracellular segments (loops) of hydrophilic residues. The amino terminus (NH $_2$) and carboxy terminus (COOH) of the protein lie on the extracellular side of the membrane.

B. The membrane-spanning regions of an ion channel protein can be identified using a hydrophobicity plot. Here a running

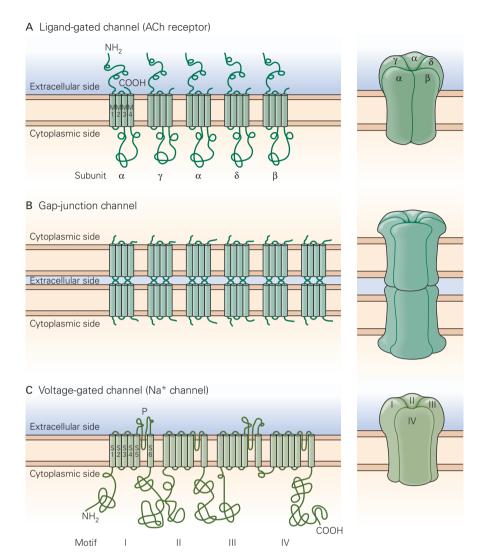

average of hydrophobicity is plotted for the entire amino acid sequence of the α -subunit of the nicotinic ACh receptor. Each point in the plot represents an average hydrophobic index of a sequence of 19 amino acids and corresponds to the midpoint of the sequence. The amino acid sequence of the subunit is inferred from the nucleotide sequence of the cloned receptor subunit gene. Four of the hydrophobic regions (M1–M4) correspond to the membrane-spanning segments. The hydrophobic region at the far left in the plot is the signal sequence that positions the hydrophilic amino terminus of the protein on the extracellular surface of the cell during protein synthesis. The signal sequence is cleaved from the mature protein. (Reproduced, with permission, from Schofield et al. 1987.)

Figure 5–11 Three superfamilies of ion channels.

A. Members of a large family of ligand-gated channels, such as the acetylcholine receptor channel, have five closely related subunits, each of which contains four transmembrane α -helixes (M1–M4). Each cylinder in the figure represents a single transmembrane α -helix.

B. The gap-junction channel is formed from a pair of hemichannels, one each in the pre- and postsynaptic cell membranes that join in the space between two cells. Each hemichannel is made of six identical subunits, each containing four transmembrane α -helixes. Gap-junction channels serve as conduits between the cytoplasm of the pre- and postsynaptic cells at electrical synapses (see Chapter 8).

C. The voltage-gated Na $^+$ channel is formed from a single polypeptide chain that contains four homologous domains or repeats (motifs I–IV), each with six membrane-spanning α -helixes (S1–S6). The S5 and S6 segments are connected by an extended strand of amino acids, the P-region, which dips into and out of the external surface of the membrane to form the selectivity filter of the pore.

transmembrane α -helixes (Figure 5–11A). In addition, the extracellular domain that forms the receptor for the ligand contains a conserved loop of 13 amino acids flanked by pair of cysteine residues that form a disulfide bond. As a result, this receptor superfamily is referred to as the cys-loop receptors. Ligand-gated channels can be classified by their ion selectivity in addition to their agonist. The genes that encode glutamate receptor channels belong to a separate gene family.

Gap-junction channels, which bridge the cytoplasm of two cells at electrical synapses (see Chapter 8), are encoded by a separate gene superfamily. A gap-junction channel is composed of 12 identical subunits, each of which has four membrane-spanning segments (Figure 5–11B).

The genes that encode the voltage-gated ion channels responsible for generating the action potential belong to another family. These channels are usually activated by membrane depolarization and are selective for Ca²⁺, Na⁺, or K⁺. All voltage-gated channels have a similar architecture, with a core motif composed of six transmembrane segments termed S1–S6 (Figure 5-11C). The S5 and S6 segments are connected by a highly conserved P-region, which loops into and out of the extracellular face of the membrane and forms the selectivity filter of the channel. Voltage-gated Na⁺ and Ca²⁺ channels are composed of a large subunit that contains four repeats of this basic motif. Voltage-gated K⁺ channels are composed of four separate subunits, each containing one motif. This structure is shared by other, more distantly related channel families (see Chapter 7).

The major gene family encoding the voltage-gated K^+ channels is distantly related to two families of K^+ channels, each with distinctive properties and structure (Figure 5–12). One family consists of the genes encoding inward-rectifying K^+ channels, which are open at the resting potential and close rapidly during depolarization. Each channel subunit has only two transmembrane segments connected by a pore-forming P-region. A second family is composed of subunits with two repeated pore-forming segments. These channels may also contribute to the resting K^+ conductance.

The sequencing of the genomes of a variety of species has led to the identification of additional ion channel gene families, found in organisms from bacteria to humans. Channels with related P-regions have been identified that are only very distantly related to the family of voltage-gated channels. These channels include the glutamate-gated channels, in which the P-region is inverted: It enters and leaves the internal surface of the membrane (see Figure 5–12D).

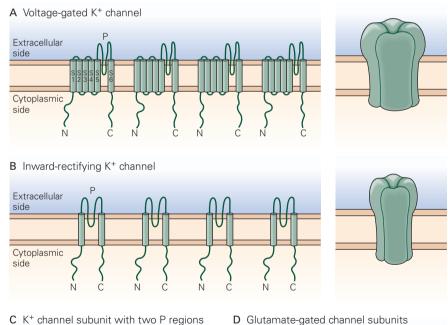

Finally, the transient receptor potential (TRP) family of nonselective cation channels (named after a mutant *Drosophila* strain in which light evokes an abnormal transient receptor potential in photoreceptors) comprises a very large group of channels that contain a P-region. Like the voltage-gated K⁺ channels, TRP channels also contain six transmembrane segments but are usually gated by intracellular ligands. TRP channels are important for Ca²⁺ metabolism in all cells, visual signaling in insects, and pain, heat, and cold sensation in the nervous system of higher animals. Recent evidence implicates TRP channels in mechanosensation and hearing in insects and fish and in certain taste sensations in mammals.

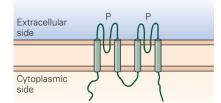

A number of other families of channels have been identified, distinct from those considered above. These include Cl⁻ channels that help set the resting potential of certain nerve and skeletal muscle cells, and a class of ligand-gated cation channels activated by ATP, which functions as a neurotransmitter at certain synapses.

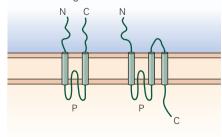

Figure 5–12 Four related families of ion channels with P-regions

A. Voltage-gated K⁺ channels are composed of four subunits. Each K⁺ channel subunit corresponds to one repeated domain of a voltage-gated Na⁺ channel, with six transmembrane segments and a pore-forming P-region.

- B. Inward-rectifying K⁺ channels are composed of four subunits, each of which has only two transmembrane segments connected by a P-region.
- C. A third type of K⁺ channel is composed of subunits that contain two repeats of the inward-rectifying K⁺ channel subunit, with each repeat containing a P-region. Two of these subunits are presumed to form a channel with four P-regions.
- D. Glutamate receptor channels form a distinct P-region channel family. In these receptors the amino terminus is extracellular and the P-region enters and exits the cytoplasmic side of the membrane. The bacterial GluR0 subunit contains two transmembrane segments (left). In higher organisms the subunits contain a third transmembrane segment (right).

With the completion of the human genome project, it is likely that nearly all of the major classes of ion channel genes have now been identified.

However, the diversity of ion channels is even greater than the large number of ion channel genes. Because most channels in a given subfamily are composed of multiple subunits, each of which may be encoded by a family of closely related genes, combinatorial permutations of these subunits can generate a diverse array of heteromultimeric channels with different functional properties. Further diversity can be produced by alternative splicing of precursor mRNA transcribed from a single gene. Finally, the sequence of a transcript can be altered by a process termed RNA editing. As with enzyme isoforms, variants of a channel with slightly different properties may be expressed at distinct stages of development (Figure 5–13), in different cell types throughout the brain (Figure 5–14), and even in different regions within a cell. These subtle variations in structure and function presumably allow channels to perform highly specific functions.

The rich variety of ion channels in different types of neurons may make it possible to develop drugs that can activate or block channels in selected regions of the nervous system. Such drugs would, in principle, have maximum therapeutic effectiveness with minimum side effects.

The Closed and Open Structures of Potassium Channels Have Been Resolved by X-Ray Crystallography

Rod MacKinnon and his colleagues provided the first high-resolution X-ray crystallographic analysis of the molecular architecture of an ion-selective channel. To overcome the difficulties inherent in obtaining crystals of integral membrane proteins, they initially focused on a bacterial K⁺ channel, termed KcsA. These channels were useful for crystallography as they can be expressed at high levels for purification, are relatively small, and have a simple transmembrane topology that is similar to inward-rectifier K⁺ channels present in higher organisms, including mammals (see Figure 5–12B). The structure of the channel was further simplified using molecular engineering to truncate cytoplasmic regions that are not essential for forming the ion-selective pore.

The crystal structure determined from the modified KcsA protein provides several important insights into the mechanisms by which the channel facilitates the movement of K^+ ions across the hydrophobic lipid bilayer. The channel is made up of four identical subunits arranged symmetrically around a central

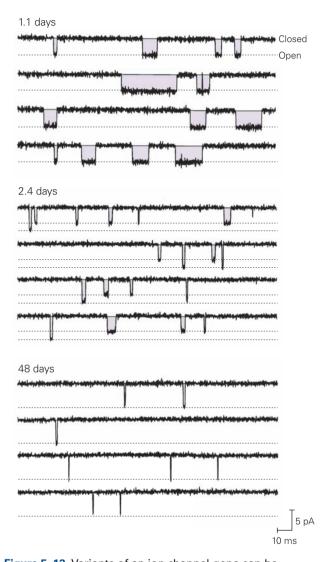

Figure 5-13 Variants of an ion channel gene can be expressed at different points in development to fine tune channel properties. These examples of currents through individual acetylcholine receptor channels were recorded from frog skeletal muscle at three stages of development: early (1.1 days), intermediate (2.4 days), and late (48 days). In immature muscle the single channels have a relatively small conductance and a relatively long open time. In mature muscle the channel conductance is larger and the average open time is shorter. At intermediate stages of development the population of channel variants is mixed; both brief, large-conductance channel openings and longer-lasting, small-conductance channel openings are evident. This functional difference results from a developmental switch in subunit composition caused by a change in gene expression. Both immature and mature forms of the receptor have α -, β -, and δ -subunits. However, the γ-subunit expressed early in development is replaced by the ε-subunit as the animal matures. (Reproduced, with permission, from Owens and Kullberg 1989.)

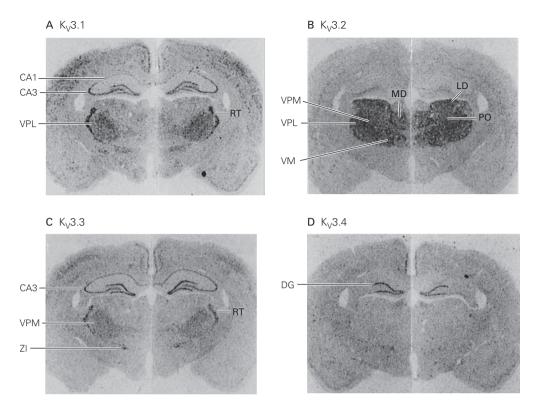

Figure 5–14 Variants of a potassium channel are expressed in different regions of the brain. Autoradiograms show the expression patterns of mRNA transcripts of the four genes comprising the K_v3 subfamily of voltage-gated K^+ channel subunits (determined by in situ hybridization). In each autoradiogram the dark areas represent high densities of expression. The brain was

sectioned at the level of the posterior thalamus. The thalamic nuclei shown are VPL, ventral posterior lateral; VPM, ventral posterior medial; MD, medial dorsal; LD, lateral dorsal; VM, ventromedial; PO, posterior; and RT, reticular. Hippocampal regions CA1 and CA3; DG, dentate gyrus; and ZI, zona incerta. (Reproduced, with permission, from Weiser et al. 1994.)

pore (Figure 5–15A). Each subunit has two membrane-spanning α -helixes, an inner and outer helix, that are connected by the P-loop, which forms the selectivity filter of the channel. At the extracellular end of the channel the two α -helixes tilt away from the central axis of the pore so that the structure resembles an inverted teepee.

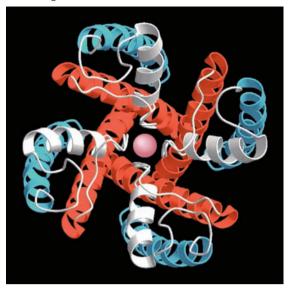

The four inner α -helixes from each of the subunits line the cytoplasmic end of the pore. At the intracellular mouth of the channel these four helixes cross, forming a very narrow opening—the "smoke hole" of the teepee. The inner helixes are homologous to the S6 membrane-spanning segment of voltage-gated K⁺ channels. At the extracellular end of the channel the pair of transmembrane helixes from each subunit are connected by a region consisting of three elements: (1) a chain of amino acids that surrounds the mouth of the channel (the turret region); (2) an abbreviated α -helix (the pore helix) approximately 10 amino acids in length that projects toward the central axis of the pore; and (3) a stretch of

5 amino acids near the C-terminal end of the P-region that forms the selectivity filter (Figure 5–15B).

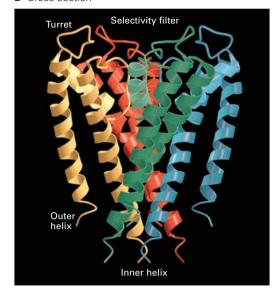

The shape and structure of the pore determine its ion-conducting properties. Both the inner and outer mouths of the pore are lined by acidic amino acids with negative charges that help attract cations from the bulk solution. Going from inside to outside, the pore consists of a medium wide tunnel 18 Å in length that leads into a wider (10 Å diameter) spherical inner chamber (Figure 5–15D). This chamber is lined predominantly by the side chains of hydrophobic amino acids. These relatively wide regions are followed by the very narrow selectivity filter, only 12 Å in length, which is ratelimiting for the passage of ions. A high ion throughput rate is ensured by the fact that the inner 28 Å of the pore, from the cytoplasmic entrance to the selectivity filter, lacks polar groups that could delay ion passage by binding and unbinding the ion.

An ion passing from the polar solution through the nonpolar lipid bilayer encounters the least energetically

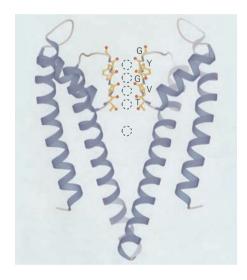

A Looking down the channel

B Cross section

D K+ ion movements

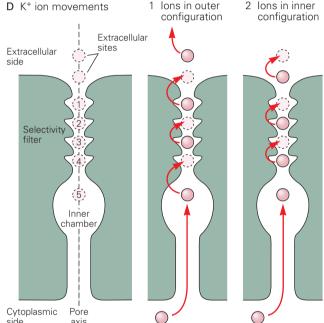

Figure 5–15 The X-ray crystal structure of a bacterial potassium channel. (Reproduced, with permission, from Doyle et al. 1998.)

A. Each of the four subunits of the K+ channel KcsA contributes two membrane-spanning helixes, the outer helix (blue) and the inner helix (red). The P-region (white) lies near the extracellular surface of the channel pore and consists of a short α -helix (pore helix) and a loop that forms the selectivity filter of the channel. A K⁺ ion is in the center of the pore. The view is looking down the channel from outside the cell.

B. The channel is seen in a cross section in the plane of the membrane. The four subunits are shown in different colors.

C. Another view in the same orientation as in part B shows only two of the four subunits. The channel contains five K⁺ binding sites (dashed). Four of the sites lie in the selectivity filter (vellow) and the fifth site lies in an inner chamber near the center of the channel. The four K⁺ binding sites of the selectivity filter are formed by successive rings of oxygen atoms (red) from five amino acid residues per subunit. Four of the rings are formed by carbonyl oxygen atoms from the main chain backbone of four consecutive amino

acid residues—glycine (G), tyrosine (Y), glycine (G), and valine (V). A fifth ring of oxygen near the internal end of the selectivity filter is formed by the side-chain hydroxyl oxygen of threonine (T). Each ring contains four oxygen atoms, one from each subunit. Only the oxygen atoms from two of the four subunits are shown in this view. (Reproduced, with permission, from Zhou et al. 2001.)

D. A view of ion permeation through the channel illustrates the changes in occupancy of the various K⁺ binding sites. A pair of ions hops in concert between a pair of binding sites in the selectivity filter. In the initial state, the "outer configuration," a pair of ions is bound to sites 1 and 3. As an ion enters the inner mouth of the channel, the ion in the inner chamber jumps to occupy the innermost binding site of the selectivity filter (site 4). This causes the pair of ions in the outer configuration to hop outward, expelling an ion from the channel. The two ions now in the inner configuration (sites 2 and 4) can hop to binding sites 1 and 3, returning the channel to its initial state (the outer configuration), from which it can conduct a second K⁺ ion. (Adapted, with permission, from Miller 2001.)

favorable region in the middle of the bilayer. The high energetic cost for a K⁺ ion to enter this region is minimized by two details of channel structure. The inner chamber is filled with water, which provides a highly polar environment, and the pore helixes provide a dipole whose electronegative carboxyl ends point toward this inner chamber (Figures 5–15C and 5–18A).

The high energetic cost incurred as a K⁺ ion sheds its waters of hydration is partially compensated by the presence of 20 oxygen atoms that line the walls of the selectivity filter and form favorable electrostatic interactions with the permeant ion. Each of the four subunits contributes four main-chain carbonyl oxygen atoms from the protein backbone and one side-chain hydroxyl oxygen atom to form a total of four binding sites for K⁺ ions. Each bound K⁺ ion is thus stabilized by interactions with a total of eight oxygen atoms, which lie in two planes above and below the bound cation. In this way the channel is able to compensate for the loss of the K⁺ ion's waters of hydration. The amino acid side chains of the selectivity filter, which are directed away from the central axis of the channel, help to stabilize the filter at a critical width, such that it provides optimal electrostatic interactions with K⁺ ions as they pass but is too wide for smaller Na⁺ ions to interact effectively with all eight carbonyl oxygens atoms at any point along the length of the filter (Figure 5–15C).

In light of the extensive interactions between a K^+ ion and the channel, how does the KcsA channel manage its high rate of conduction? Although the channel contains a total of five potential binding sites for K^+ ions—four in the selectivity filter and one in the inner chamber—X-ray analysis shows that the channel can be occupied by at most three K^+ ions at any instant. One ion is normally present in the wide inner chamber, and two ions occupy two of the four binding sites within the selectivity filter (Figure 5–15D). Because of electrostatic repulsion, two K^+ ions never simultaneously occupy adjacent binding sites within the selectivity filter; rather, a water molecule is always interspersed between K^+ ions.

During conduction a pair of K^+ ions within the selectivity filter hop in tandem between pairs of binding sites. If only one ion were in the selectivity filter it would be bound rather tightly, and the throughput rate for ion permeation would be compromised. But the mutual electrostatic repulsion between two K^+ ions occupying nearby sites ensures that the ions will linger only briefly, thus resulting in a high overall rate of K^+ conduction.

X-ray crystallographic analysis has also begun to provide insight into the conformational changes that underlie the opening and closing of K⁺ channels. Studies by Clay

Armstrong in the 1960s suggested that a gate exists at the intracellular mouth of voltage-gated K^{+} channels of higher organisms. Small organic compounds such as tetraethylammonium can enter and block the channel only when this internal gate is opened by depolarization. We now know that this internal gate is the narrow opening formed by the crossing of the four α -helixes at the intracellular mouth of the channel. The small opening at the helix bundle crossing in KcsA revealed by X-ray crystallography turns out to be too narrow to allow ions to pass. Thus the X-ray crystal structure is that of a closed channel.

What do K⁺ channels look like when they are open? Although we do not know the answer for KcsA, MacKinnon and his colleagues determined the open structure for a related bacterial K⁺ channel, MthK. Each subunit of this channel has two transmembrane segments, similar to KcsA. Unlike KcsA, MthK has a cytoplasmic binding domain for Ca²⁺ and can be opened by high concentrations of internal Ca2+. MacKinnon and colleagues determined the structure of the open state by growing crystals of MthK in the presence of Ca²⁺. Remarkably, the inner helixes that form the tight bundle crossing in KcsA are bent in MthK at a flexible glycine residue that causes them to splay outward, forming an internal orifice that is dilated to 20 Å in diameter, wide enough to pass K⁺ as well as larger compounds such as tetraethylammonium (Figure 5–16). This mechanism is likely to be a general one because the inner helixes of many K⁺ channels of bacteria and higher organisms have a conserved glycine residue at this position. The presence of a bend at this glycine gating hinge was recently confirmed in the X-ray crystal structure of a mammalian voltage-gated K⁺ channel.

The Structural Basis of Chloride Selectivity Reveals a Close Relation Between Ion Channels and Ion Transporters

Ions move across cell membranes by active transport by ion transporters (or pumps) as well as diffusion through ion channels. Ion transporters are distinguished from ion channels because (1) they require a source of energy to actively transport ions against their electrochemical gradients and (2) they transport ions at rates much lower than those of ion channels, too low to support fast neuronal signaling. Nevertheless, some types of transporters and certain ion channels may have a similar structure according to studies of a bacterial membrane protein that transports protons and Cl⁻. These studies also yield insights into the structural basis for Cl⁻ channel selectivity.

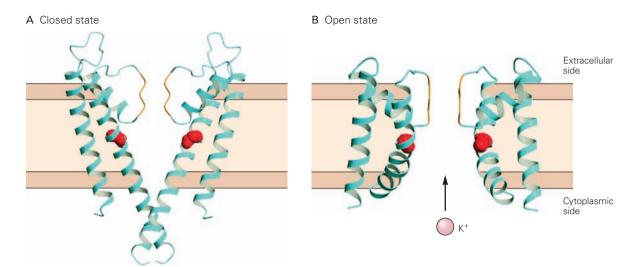

Figure 5–16 Gating of bacterial potassium channels. Only two of four subunits are shown.

A. In the closed state the internal mouth of the pore formed by the inner helixes is too narrow to allow K^+ to pass (based on the X-ray crystal structure of the KcsA channel).

B. In the open state the inner helixes are bent at a conserved glycine residue (red), widening the internal mouth of the pore (based on the X-ray crystal structure of the MthK channel). (Reproduced, with permission, from Yu et al. 2005; after Jiang et al. 2002.)

A large family of Cl⁻ channels, the ClC channels, is widely expressed in neurons and other cells of vertebrates. In vertebrate skeletal muscle the ClC-1 channels are important in maintaining the resting potential. Mutations in the genes for these channels underlie certain inherited forms of myotonia; the loss of Cl⁻ channel activity leads to a depolarizing after-potential following an action potential, resulting in repetitive firing of action potentials that produces abnormally prolonged muscle contraction. MacKinnon and his colleagues obtained a highresolution X-ray crystal structure for a CIC protein from the bacterium Escherichia coli. Based on the close similarity of their amino acid sequences, it seems likely that the three-dimensional structures of the *E. coli* protein and vertebrate CIC channels would be very similar. Indeed, the E. coli CIC structure is consistent with the findings of a large number of previous studies of the effects of mutagenesis of vertebrate ClC channels.

It therefore came as a surprise when Chris Miller and colleagues found that the *E. coli* ClC is a transporter, not a channel. The *E. coli* ClC transporter uses the energy stored in a H⁺ gradient across the cell membrane to move Cl⁻ against its electrochemical gradient from the inside of the cell to the outside in exchange for the transport of H⁺ from the outside of the cell to the inside, down its electrochemical gradient. This type of transporter is termed an ion exchanger. In the *E. coli* ClC two Cl⁻ ions are transported in

exchange for one proton. The rate of Cl⁻ transport through the *E. coli* ClC by this exchange mechanism is 100- to 1,000-fold slower than that of vertebrate ClC channels.

The E. coli ClC protein, similar to vertebrate ClC channels, is a homodimer composed of two identical subunits. Each vertebrate CIC channel subunit forms a separate Cl⁻-conducting pore that gates independently from the other half (Figure 5–17A,B). The structure of the E. coli ClC transporter is much more complex than that of a K⁺ channel. Each subunit contains 18 α-helixes divided into related N-terminal and C-terminal halves. each containing nine helixes (Figure 5-17C,D). Surprisingly, the two halves are found in a head-to-head arrangement so that the helixes in each half have an opposite orientation in the membrane (helix 1 is related to helix 18, not helix 10). Unlike the pore of a K⁺ channel, which is widest in the central region, each pore of the *E. coli* ClC has an hourglass profile (Figure 5–18B). The neck of the hourglass, a tunnel 12 Å in length that forms the selectivity filter, is just wide enough to contain fully dehydrated Cl⁻ ions.

Although the structures of the *E. coli* ClC transporter and K⁺ channel differ in significant respects, the two structures have evolved in four similar ways to achieve a high degree of ion selectivity. First, both can be occupied by multiple ions. The *E. coli* ClC contains three binding sites for Cl⁻ ions within each selectivity filter. It appears that they can all be occupied

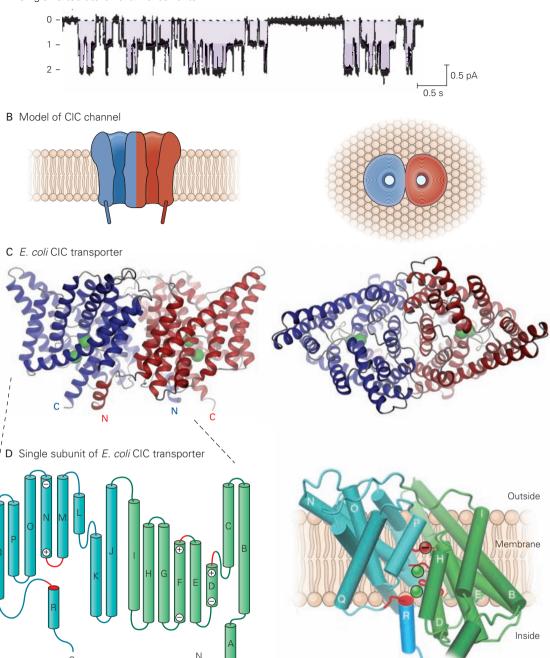

Figure 5–17 The vertebrate CIC family of chloride channels and transporters are double-barrel channels with two identical pores.

A. Recordings of current through a single vertebrate Cl⁻ channel show three levels of current: both pores closed (0), one pore open (1), and both pores open (2). (Reproduced, with permission, from Miller 1982.)

B. The CIC channels are dimers composed of two identical subunits, each forming a CI⁻-selective pore. The channel is shown from the side (left) and looking down on the membrane from outside the cell (right). Each subunit contains its own ion transport pathway and gate. In addition, the dimer has a gate shared by both subunits (not shown). The drawing illustrates the functional properties of the channel.

C. The X-ray crystal structure of the *Escherichia coli* CIC CI^/H $^+$ exchanger in a side view (left) and top-down view (right). The ribbon diagram shows that each subunit is composed of a large

number of α -helixes. Two Cl $^-$ ions (green spheres) are shown bound to each subunit: one ion is bound to the selectivity filter and a second is bound to an internal site closer to the cytoplasmic side of the membrane. (Reproduced, with permission, from Dutzler et al. 2002; Dutzler 2004.)

D. Left: The linear arrangement of the two cytoplasmic helixes (A and R) and 16-membrane helixes (B–Q) in a single subunit of the *E. coli* CIC transporter. The helixes from the N-terminal half of a subunit are shown in green, while the helixes from the C-terminal half are shown in cyan. (Reproduced, with permission, from Dutzler et al. 2002.) Right: The three-dimensional arrangement of the helixes in a single *E. coli* CIC subunit. The regions in red help form the CI⁻ permeation path. The CI⁻ ions at the selectivity filter (top) and an internal site (bottom) are illustrated as green spheres. A negative charge on the channel wall that may serve as the channel's gate is illustrated as a red sphere. (Reproduced, with permission, from Jentsch 2002.)

simultaneously, thus creating a metastable state that ensures that the ions pass through the pore quickly. Second, in both cases the ion binding sites are formed by polar, partially charged atoms, not by fully ionized atoms. Thus the Cl⁻ binding sites are formed by main chain amide nitrogen atoms, which bear a partial positive charge, and by side-chain hydroxyl groups. The binding energy provided by these polar groups is relatively weak, ensuring that the Cl⁻ ions do not become too tightly bound. Third, in both structures permeant ions are stabilized in the center of the membrane by the partial charges of α helixes (Figure 5–18). In *E. coli* CIC the positively polarized (N-terminal) ends of two α-helixes dip partway into the membrane to lower the energetic barrier for Cl⁻ ions within the nonpolar environment of the membrane. Fourth, in both cases wide water-filled vestibules at either end of the selectivity filter allow ions to approach the filter in a partially hydrated state (see Figure 5–18).

Thus we see that, although the K⁺ channel and *E. coli* ClC pores differ fundamentally in amino acid sequence and in secondary, tertiary, and quaternary structures, strikingly similar functional features have evolved in these two classes of membrane proteins to ensure both a high degree of ion selectivity and efficient throughput. These features have been conserved with surprising fidelity from prokaryotes through humans.

Why does the *E. coli* ClC function as a H⁺/Cl⁻ exchanger, whereas the vertebrate ClC proteins function as conventional channels? A likely explanation is that, unlike ion channels, the *E. coli* ClC does not have a continuous open pathway for ion movement from the outside of the membrane to the inside. Rather, like other pumps it is thought to have two gates, one external and one internal. Importantly, the two gates would never open simultaneously. Rather, ion movements and gate movements are presumed to be highly coupled in a tight cycle of reactions (Figure 5–19).

The relatively slow opening and closing of two gates in each cycle of ion transport, which takes place on a scale of milliseconds, explains why the rate of ion transfer through a transporter is several orders of magnitude slower than that of an ion channel. In the crystal structure of the *E. coli* ClC transporter the Cl⁻ ion in the selectivity filter is trapped by a negatively charged side chain of a nearby glutamate residue on one side and an electronegative hydroxyl group from a serine residue on the other side. Protonation of this glutamate is likely to cause its side chain to rotate out of the way, permitting Cl⁻ movement.

One or both of the *E. coli* ClC gates is thought to be missing in vertebrate ClC channels, providing an unobstructed pathway for the rapid diffusion of Cl⁻down its electrochemical gradient. Thus, despite the

direction to stabilize a ${\sf K}^{\scriptscriptstyle +}$ ion in the internal vestibule of the channel.

B. In Cl⁻ channels the two pore helixes are in an antiparallel arrangement. Their positive dipole ends point toward the center of the channel to stabilize a Cl⁻ ion in the middle of the channel. Only one subunit of the dimeric Cl⁻ channel is shown.

Figure 5–19 The functional difference between ion channels and pumps. (Adapted, with permission, from Gadsby 2004.)

- A. Channels have a continuous aqueous pathway for ion conduction across the membrane. This pathway can be occluded by the closing of a gate.
- B. Pumps have two gates in series that control ion flux. The gates are never open simultaneously, but both can close to trap one or more ions in the pore. The type of pump illustrated here moves two different types of ions in opposite directions and is termed an exchanger or antiporter. Ion movement is tightly linked to a cycle of opening and closing of the two gates. When the external gate is open, one type of ion (red) leaves while the other type (blue) enters the channel (1). This triggers a conformational change, causing the external gate to shut, thereby trapping the incoming ion (2). A second conformational change then causes the internal gate to open, allowing the trapped ion to leave and a new ion to enter (3). A further conformational change opens the external gate, allowing the cycle to continue (4). With each cycle, one type of ion is transported from the outside to the inside of the cell, whereas the other type is transported from the inside to the outside of the cell. By coupling the movements of two or more ions, an exchanger can use the energy stored in the concentration gradient of one ion to actively transport another ion against its concentration gradient.

conservation of certain fundamental mechanisms in ClC proteins, relatively small structural changes give rise to two very distinct mechanisms of ion transport.

An Overall View

In all cells ion channels permit the flow of ions across an otherwise impermeable membrane. In nerve and muscle cells ion channels are important for controlling the rapid changes in membrane potential associated with the action potential, receptor potentials and postsynaptic potentials of target cells. In addition, the influx of Ca²⁺ ions controlled by these channels can alter many metabolic processes within cells, leading to the activation of various enzymes and other proteins, release of neurotransmitter, and even changes in gene expression.

Channels differ in their ion selectivity and in the factors that control their opening and closing, or gating. Ion selectivity is achieved through physical–chemical interactions between the ion and various amino acid residues that line the walls of the channel pore. Gating involves a change of the channel's conformation in response to an extrinsic stimulus, such as voltage, a ligand, or stretch or pressure.

Three methodological advances have greatly increased our understanding of channel function. First, the patch-clamp technique has made it possible to record the current through single channels. Second, genome-wide sequencing has determined the primary amino acid sequences of nearly all genes that encode ion channels. From these results many of the channels described so far can be grouped into three major gene families: voltage-gated channels and related subfamilies, a large family of ligand-gated channels, and gap-junction channels. Finally, X-ray crystallography has provided a detailed view of the three-dimensional structure of two types of channels.

The activity of channels can be modified by cellular metabolic reactions, including protein phosphorylation; by various ions that act as blockers; and by toxins, poisons, and drugs. Channels are also important targets in various diseases. Certain autoimmune neurological disorders, such as myasthenia gravis, result from the actions of specific antibodies that interfere with channel function. Other diseases, such as hyperkalemic periodic paralysis, result from ion channel defects because of genetic mutations. Detailed knowledge of the genetic basis of channel structure and function may one day make it possible to devise more specifically targeted pharmacological therapies for various neurological and psychiatric disorders.

An Overall View

Information is carried within neurons and from neurons to their target cells by electrical and chemical signals. Transient electrical signals are particularly important for carrying time-sensitive information rapidly and over long distances. These transient electrical signals—receptor potentials, synaptic potentials, and action potentials—are all produced by temporary changes in the electric current into and out of the cell, changes that drive the electrical potential across the cell membrane away from its resting value. This current represents the flow of negative and positive ions through ion channels in the cell membrane.

Two types of ion channels—resting and gated—have distinctive roles in neuronal signaling. Resting channels are primarily important in maintaining the resting membrane potential, the electrical potential across the membrane in the absence of signaling. Some types of resting channels are constitutively open and are not gated by changes in membrane voltage; other types are gated by voltage but can open at the negative resting potential of neurons. Most voltage-gated channels, in contrast, are closed when the membrane is at rest and require membrane depolarization to open.

In this and the next several chapters we consider how transient electrical signals are generated in the neuron. We begin by discussing how resting ion channels establish and maintain the resting potential and briefly describe the mechanism by which the resting potential can be perturbed, giving rise to transient electrical signals such as the action potential. We then consider how the passive electrical properties of neurons—their resistive and capacitive characteristics—contribute to the integration and local propagation of synaptic and receptor potentials within the neuron. In Chapter 7

we shall examine the detailed mechanisms by which voltage-gated Na⁺, K⁺, and Ca²⁺ channels generate the action potential, the electrical signal conveyed along the axon. Synaptic and receptor potentials are considered in Chapters 8 to 11 in the contexts of synaptic signaling between neurons and sensory reception.

The Resting Membrane Potential Results from the Separation of Charge Across the Cell Membrane

The neuron's cell membrane has thin clouds of positive and negative ions spread over its inner and outer surfaces. At rest the extracellular surface of the membrane has an excess of positive charge and the cytoplasmic surface an excess of negative charge (Figure 6–1). This separation of charge is maintained because the lipid bilayer of the membrane is a barrier to the diffusion of ions, as explained in Chapter 5. The charge separation gives rise to a difference of electrical potential, or

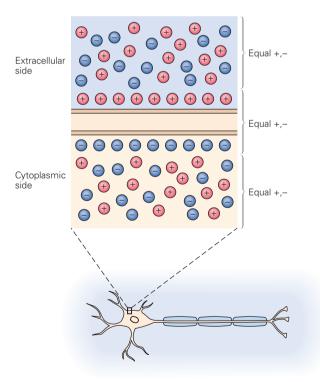

Figure 6–1 The cell membrane potential results from the separation of net positive and net negative charges on either side of the membrane. The excess of positive ions outside the membrane and negative ions inside the membrane represents a small fraction of the total number of ions inside and outside the cell at rest.

voltage, across the membrane called the *membrane* potential (V_m) , defined as

$$V_{\rm m} = V_{\rm in} - V_{\rm out}$$

where $V_{\rm in}$ is the potential on the inside of the cell and $V_{\rm out}$ the potential on the outside.

The membrane potential of a cell at rest is called the *resting membrane potential* ($V_{\rm r}$). Since by convention the potential outside the cell is defined as zero, the resting potential is equal to $V_{\rm in}$. Its usual range is -60 mV to -70 mV. All electrical signaling involves brief changes in the resting membrane potential that are caused by electrical currents across the cell membrane.

The electric current is carried by ions, both positive (cations) and negative (anions). The direction of current is conventionally defined as the direction of net movement of positive charge. Thus, in an ionic solution cations move in the direction of the electric current and anions move in the opposite direction. In the nerve cell at rest there is no net charge movement across the membrane. When there is a net flow of cations or anions into or out of the cell, the charge separation across the resting membrane is disturbed, altering the electrical potential of the membrane. A reduction or reversal of charge separation, leading to a less negative membrane potential, is called depolarization. An increase in charge separation, leading to a more negative membrane potential, is called hyperpolarization.

Changes in membrane potential that do not lead to the opening of gated ion channels are passive responses of the membrane and are called *electrotonic potentials*. Hyperpolarizing responses are almost always passive, as are small depolarizations. However, when depolarization approaches a critical level, or threshold, the cell responds actively with the opening of voltage-gated ion channels, which produces an all-or-none *action potential* (Box 6–1).

The Resting Membrane Potential Is Determined by Nongated and Gated Ion Channels

The resting membrane potential is the result of the passive flux of individual ion species through several classes of resting channels. Understanding how this passive ionic flux gives rise to the resting potential enables us to understand how the gating of different types of ion channels generates the action potential, as well as the receptor and synaptic potentials.

Box 6-1 Recording the Membrane Potential

Reliable techniques for recording the electrical potential across cell membranes were developed in the late 1940s. These techniques allow accurate recordings of both the resting membrane potential and action potentials.

Glass micropipettes filled with a concentrated salt solution serve as electrodes and are placed on either side of the cell membrane. Wires inserted into the back ends of the pipettes are connected via an amplifier to an oscilloscope, which displays the amplitude of the membrane potential in volts. Because the diameter of a microelectrode tip is small (< 1 μm), it can be inserted into a cell with relatively little damage to the cell membrane.

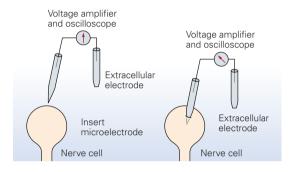

Figure 6-2A The recording setup.

When both electrodes are outside the cell, no electrical potential difference is recorded. But as soon as one microelectrode is inserted into the cell, the oscilloscope shows a steady voltage, the resting membrane potential. In most nerve cells at rest the membrane potential is approximately –65 mV.

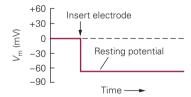

Figure 6-2B Oscilloscope display.

The membrane potential can be experimentally changed using a current generator connected to a second pair of electrodes—one intracellular and one extracellular. When the intracellular electrode is made positive with respect to the extracellular one, a pulse of positive current from the current generator causes positive charge to flow into the neuron from the intracellular electrode. This current returns to the extracellular electrode by flowing outward across the membrane.

As a result, the inside of the membrane becomes more positive while the outside of the membrane becomes more negative. This progressive *decrease* in the normal separation of charge is called *depolarization*.

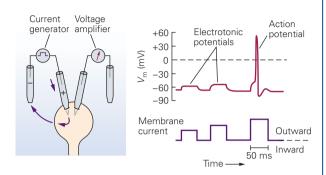

Figure 6-2C Depolarization.

Small depolarizing current pulses evoke purely electrotonic (passive) potentials in the cell—the size of the change in potential is proportional to the size of the current pulses. However, a sufficiently large depolarizing current triggers the opening of voltage-gated ion channels. The opening of these channels leads to the action potential, which differs from electrotonic potentials in the way in which it is generated as well as in magnitude and duration.

Reversing the direction of current—making the intracellular electrode negative with respect to the extracellular electrode—makes the membrane potential more negative. This *increase* in charge separation is called *hyperpolarization*.

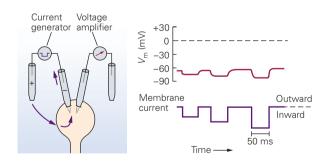

Figure 6-2D Hyperpolarization.

The responses of the cell to hyperpolarization are usually purely electrotonic—as the size of the current pulse increases, the hyperpolarization increases proportionately. Hyperpolarization does not trigger an active response in the cell.

Species of ion	Concentration in cytoplasm (mM)	Concentration in extracellular fluid (mM)	Equilibrium potential ¹ (mV)
K ⁺	400	20	-75
Na ⁺	50	440	+55
Cl-	52	560	-60
A- (organic anions)	385	none	none

Table 6-1 Distribution of the Major Ions Across a Neuronal Membrane at Rest: The Giant Axon of the Squid

No single ion species is distributed equally on the two sides of a nerve cell membrane. Of the four most abundant ions found on either side of the cell membrane, Na⁺ and Cl⁻ are concentrated outside the cell and K⁺ and organic anions (A⁻, primarily amino acids and proteins) inside. Table 6–1 shows the distribution of these ions inside and outside of one particularly well-studied nerve cell process, the giant axon of the squid, whose extracellular fluid has a salt concentration similar to that of seawater. Although the absolute values of the ionic concentrations for vertebrate nerve cells are two- to threefold lower than those for the squid giant axon, the *concentration gradients* (the ratio of the external to internal ion concentration) are similar.

The unequal distribution of ions raises several important questions. How do ionic gradients contribute to the resting membrane potential? What prevents the ionic gradients from dissipating by diffusion of ions across the membrane through the resting channels? These questions are interrelated, and we shall answer them by considering two examples of membrane permeability: the resting membranes of glial cells, which are permeable to only one species of ion, and the resting membranes of nerve cells, which are permeable to three. For the purposes of this discussion, we shall only consider the resting channels that are not gated by voltage and thus are always open.

Open Channels in Glial Cells Are Permeable to Potassium Only

The permeability of a cell membrane to particular ion species is determined by the relative proportions of the various types of ion channels that are open. The simplest case is that of the glial cell, which has a resting potential of approximately –75 mV. Like most cells, a glial cell has high concentrations of K⁺ and negatively charged organic anions on the inside and high concentrations of

Na⁺ and Cl⁻ on the outside. However, most resting channels in the membrane are permeable only to K⁺.

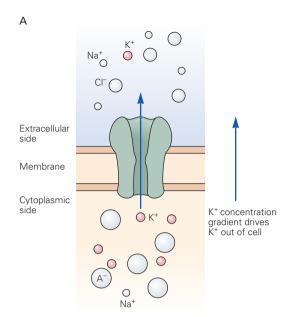

Because K⁺ ions are present at a high concentration inside the cell, they tend to diffuse across the membrane from the inside to the outside of the cell down their chemical concentration gradient. As a result, the outside of the membrane accumulates a net positive charge (caused by the slight excess of K⁺) and the inside a net negative charge (because of the deficit of K⁺ and the resulting slight excess of anions). Because opposite charges attract each other, the excess positive charges on the outside and the excess negative charges on the inside collect locally on either surface of the membrane (see Figure 6–1).

The flux of K⁺ out of the cell is self-limiting. The efflux of K⁺ gives rise to an electrical potential difference—positive outside, negative inside. The greater the flow of K⁺, the more charge is separated and the greater is the potential difference. Because K⁺ is positive, the negative potential inside the cell tends to oppose the further efflux of K⁺. Thus ions are subject to two forces driving them across the membrane: (1) a *chemical driving force*, a function of the concentration gradient across the membrane, and (2) an *electrical driving force*, a function of the electrical potential difference across the membrane.

Once K^+ diffusion has proceeded to a certain point, the electrical driving force on K^+ exactly balances the chemical driving force. That is, the outward movement of K^+ (driven by its concentration gradient) is equal to the inward movement of K^+ (driven by the electrical potential difference across the membrane). This potential is called the K^+ equilibrium potential, E_K (Figure 6–3). In a cell permeable only to K^+ ions, E_K determines the resting membrane potential, which in most glial cells is approximately -75 mV.

The equilibrium potential for any ion *X* can be calculated from an equation derived in 1888 from basic

¹The membrane potential at which there is no net flux of the ion species across the cell membrane.

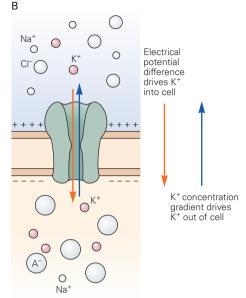

Figure 6–3 The flux of K^+ across a cell membrane is determined by both the K^+ concentration gradient and the membrane potential.

A. In a cell permeable only to K^+ , the resting potential is generated by the efflux of K^+ down its concentration gradient.

B. The continued efflux of K⁺ builds up an excess of positive charge on the outside of the cell and leaves behind an excess

of negative charge inside the cell. This buildup of charge leads to a potential difference across the membrane that impedes the further efflux of K^+ , so eventually an equilibrium is reached: The electrical and chemical driving forces are equal and opposite, and as many K^+ ions move in as move out.

thermodynamic principles by the German physical chemist Walter Nernst:

$$E_{\rm x} = \frac{RT}{zF} \ln \frac{[{\rm X}]_{\rm o}}{[{\rm X}]_{\rm i}}$$
, Nernst Equation

where R is the gas constant, T the temperature (in degrees Kelvin), z the valence of the ion, F the Faraday constant, and $[X]_o$ and $[X]_i$ the concentrations of the ion outside and inside the cell. (To be precise, chemical activities rather than concentrations should be used.)

Since RT/F is 25 mV at 25°C (77°F, room temperature), and the constant for converting from natural logarithms to base 10 logarithms is 2.3, the Nernst equation can also be written as follows:

$$E_{\rm x} = \frac{58\,\mathrm{mV}}{\mathrm{z}} \log \frac{[\mathrm{X}]_{\rm o}}{[\mathrm{X}]_{\rm i}}.$$

Thus, for K^+ , since z = +1 and given the concentrations inside and outside the squid axon in Table 6–1:

$$E_{\rm k} = \frac{58\,{\rm mV}}{1}\log\frac{[20]}{[400]} = -75\,{\rm mV}.$$

The Nernst equation can be used to find the equilibrium potential of any ion that is present on both

sides of a membrane permeable to that ion (the potential is sometimes called the *Nernst potential*). The Na⁺, K⁺, and Cl⁻ equilibrium potentials for the distributions of ions across the squid axon are given in Table 6–1.

In our discussion so far we have treated the generation of the resting potential as a passive mechanism—the diffusion of ions down their chemical gradients—one that does not require the expenditure of energy by the cell, for example through hydrolysis of adenosine triphosphate (ATP). However, energy (from ATP hydrolysis) is required to set up the initial concentration gradients and to maintain them in neurons, as we shall see below.

Open Channels in Resting Nerve Cells Are Permeable to Several Ion Species

Unlike glial cells, nerve cells at rest are permeable to Na⁺ and Cl⁻ ions in addition to K⁺ ions. Of the abundant ion species in nerve cells, only the large organic anions (A⁻) are unable to permeate the cell membrane. How are the concentration gradients for the three permeant ions (Na⁺, K⁺, and Cl⁻) maintained across the membrane of a single cell, and how do these three

gradients interact to determine the cell's resting membrane potential?

To answer these questions, it is easiest to examine first only the diffusion of K^+ and Na^+ . Let us return to the simple example of a cell having only K^+ channels, with concentration gradients for K^+ , Na^+ , Cl^- , and A^- as shown in Table 6–1. Under these conditions the resting membrane potential, $V_{\rm r}$, is determined solely by the K^+ concentration gradient and is equal to $E_{\rm K}$ (–75 mV) (Figure 6–4A).

Now consider what happens if a few resting Na⁺ channels are added to the membrane, making it slightly permeable to Na⁺. Two forces drive Na⁺ into the cell: Na⁺ tends to flow into the cell down its chemical concentration gradient, and it is driven into the cell by the negative electrical potential difference across the membrane (Figure 6–4B). The influx of Na⁺ depolarizes the cell, but only slightly from the K⁺ equilibrium potential (–75 mV). The new membrane potential does not come close to the Na⁺ equilibrium potential of +55 mV because there are many more resting K⁺ channels than Na⁺ channels in the membrane.

As soon as the membrane potential begins to depolarize from the value of the K⁺ equilibrium potential, K+ flux is no longer in equilibrium across the membrane. The reduction in the negative electrical force driving K⁺ into the cell means that there is now a net flow of K⁺ out of the cell, tending to counteract the Na⁺ influx. The more the membrane potential is depolarized and driven away from the K+ equilibrium potential, the greater is the net electrochemical force driving K⁺ out of the cell and consequently the greater the net K⁺ efflux. Eventually, the membrane potential reaches a new resting level at which the increased outward movement of K⁺ just balances the inward movement of Na⁺ (Figure 6–4C). This balance point (usually approximately -65 mV) is far from the Na⁺ equilibrium potential (+55 mV) and is only slightly more positive than the K⁺ equilibrium potential (–75 mV).

To understand how this balance point is determined, bear in mind that the magnitude of the flux of an ion across a cell membrane is the product of its *electrochemical driving force* (the sum of the electrical and chemical driving forces) and the conductance of the membrane to the ion:

ion flux = (electrical driving force + chemical driving force) × membrane conductance.

In a resting nerve cell relatively few Na⁺ channels are open, so the membrane conductance of Na⁺ is quite low. Thus, despite the large chemical and electrical forces

driving Na⁺ into the cell, the influx of Na⁺ is small. In contrast, many K⁺ channels are open in the membrane of a resting cell so that the membrane conductance of K⁺ is relatively large. Because of the high relative conductance of Na⁺ to K⁺ in the cell at rest, the small net outward force acting on K⁺ is enough to produce a K⁺ efflux equal to the Na⁺ influx.

The Electrochemical Gradients of Sodium, Potassium, and Calcium Are Established by Active Transport of the Ions

For a cell to have a steady resting membrane potential, the charge separation across the membrane must be constant over time. That is, at every instant the influx of positive charge must be balanced by the efflux of positive charge. If these fluxes were not equal, the charge separation across the membrane, and thus the membrane potential, would vary continually.

As we have seen, the passive movement of K⁺ out of the resting cell through open channels balances the passive movement of Na⁺ into the cell. However, this steady leakage of ions cannot be allowed to continue unopposed for any appreciable length of time because the Na⁺ and K⁺ gradients would eventually run down, reducing the resting membrane potential.

Dissipation of ionic gradients is prevented by the sodium-potassium pump (Na+-K+ pump), which moves Na⁺ and K⁺ against their electrochemical gradients: It extrudes Na⁺ from the cell while taking in K⁺. The pump therefore requires energy, and the energy comes from hydrolysis of ATP (Figure 6-5A). Thus at the resting membrane potential the cell is not in equilibrium but rather in a steady state: There is a continuous passive influx of Na⁺ and efflux of K⁺ through resting channels that is exactly counterbalanced by the Na+-K+ pump. As we saw in the previous chapter, pumps are similar to ion channels in that they catalyze the movement of ions across cell membranes. However they differ in two important respects. First, whereas ion channels are passive conduits that allow ions to move down their electrochemical gradient, pumps transport ions against their electrochemical gradient by expending chemical energy. Second, ion transport is much faster in channels: Ions typically flow through channels at a rate of 10^7 to 10^8 per second, whereas pumps operate at speeds more than 10,000 times slower.

The Na⁺-K⁺ pump is a large membrane-spanning protein with catalytic binding sites for Na⁺ and ATP on its intracellular surface and for K⁺ on its extracellular surface. With each cycle the pump hydrolyzes one molecule of ATP. (Because the Na⁺-K⁺ pump hydrolyzes ATP, it is also referred to as the *Na⁺-K⁺ ATPase*.)

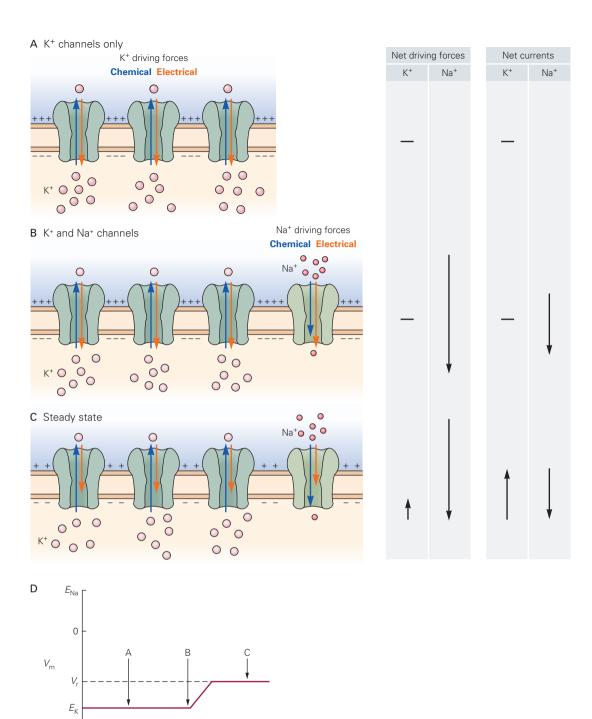

Figure 6-4 The resting potential of a cell is determined by the proportions of different types of ion channels that are open, together with the value of their equilibrium potentials. The channels in the figures represent the entire complement of K⁺ or Na⁺ channels in the cell membrane. The lengths of the arrows within the channels represent the relative amplitudes of the electrical (red) and chemical (blue) driving forces acting on Na⁺ or K⁺. The lengths of the arrows in the diagram on the right denote the relative sizes of the net driving force (the sum of the electrical and chemical driving forces) for Na⁺ and K⁺ and the net ion currents. Three hypothetical situations are illustrated.

Time -

A. In a resting cell in which only K+ channels are present, K+ ions are in equilibrium and $V_{\rm m}=E_{\rm K}.$

- **B.** Adding a few Na⁺ channels to the resting membrane allows Na⁺ ions to diffuse into the cell, and this influx begins to depolarize the membrane.
- C. The resting potential settles at a new level, where the influx of Na⁺ is balanced by the efflux of K⁺. In this example the aggregate conductance of the K⁺ channels is much greater than that of the Na⁺ channels because the K⁺ channels are more numerous. As a result, a relatively small net driving force for K⁺ drives a current equal and opposite to the Na⁺ current driven by the much larger net driving force for Na⁺. This is a steady-state condition, in which neither Na⁺ nor K⁺ is in equilibrium but the net flux of charge is null.
- D. Membrane voltage changes during the hypothetical situations illustrated in A, B, and C.

Figure 6–5 Pumps and transporters regulate the chemical concentration gradients of Na⁺, K⁺, Ca²⁺, and Cl⁻ ions.

A. The Na⁺-K⁺ pump and Ca²⁺ pump are two examples of active transporters that use the energy of adenosine triphosphate (ATP) hydrolysis to transport ions against their concentration gradient. The α -subunit of a Na⁺-K⁺ pump or homologous Ca²⁺ pump (below) has 10 transmembrane segments, a cytoplasmic amino terminus, and a cytoplasmic carboxyl terminus. There are also cytoplasmic loops important for binding ATP (N), ATP hydrolysis and phosphorylation of the pump (P), and transducing phosphorylation to transport (A). The Na⁺-K⁺ pump

also contains a smaller β -subunit with a single transmembrane domain (not shown).

B. The Na⁺-Ca²⁺ exchanger uses the potential energy of the electrochemical gradient of Na⁺ to transport Ca²⁺ out of a cell. The Na⁺-Ca²⁺ exchanger contains nine transmembrane segments, two reentrant membrane loops important for ion transport, and a large cytoplasmic regulatory loop. Chloride ions are transported into the cell by the Na⁺-K⁺- Cl⁻ cotransporter and out of the cell by the K⁺-Cl⁻ cotransporter. These transporters are members of a family of Cl⁻ transport proteins with 12 transmembrane segments.

It uses this energy of hydrolysis to extrude three Na+ ions from the cell and bring in two K⁺ ions. The unequal flux of Na⁺ and K⁺ ions causes the pump to generate a net outward ionic current. Thus, the pump is said to be electrogenic. This pump-driven efflux of positive charge tends to set the resting potential a few millivolts more negative than would be achieved by the passive diffusion mechanisms discussed above. During periods of intense neuronal activity the increased influx of Na+ leads to an increase in Na+-K+ pump activity that generates a prolonged outward current, leading to a prolonged hyperpolarizing after-potential that can last for several minutes, until the normal Na⁺ concentration is restored. The Na+-K+ pump is inhibited by ouabain or digitalis plant alkaloids, an action that is important in the treatment of heart failure.

The Na⁺-K⁺ pump is a member of a large family of pumps known as P-type ATPases (because the phosphoryl

group of ATP is temporarily transferred to the pump). P-type ATPases include a Ca²⁺ pump that transports Ca²⁺ across cell membranes (see Figure 6–5A). All cells normally maintain a very low cytoplasmic Ca2+ concentration, between 50 and 100 nM. This concentration is more than four orders of magnitude lower than the external concentration, which is approximately 2 mM. Calcium pumps in the plasma membrane transport Ca²⁺ out of the cell; other Ca²⁺ pumps located in internal membranes, such as the smooth endoplasmic reticulum, transport Ca²⁺ from the cytoplasm into these intracellular Ca²⁺ stores. Calcium pumps are thought to transport two Ca²⁺ ions for each ATP molecule that is hydrolyzed, with two protons transported in the opposite direction. The Na⁺-K⁺ pump and Ca²⁺ pump have similar structures. They are formed from 110 kD α-subunits, whose large transmembrane domain contains 10 membranespanning α -helixes (see Figure 6–5A).

Most neurons have relatively few Ca²⁺ pumps in the plasma membrane. Instead, Ca2+ is transported out of the cell by the Na⁺-Ca²⁺ exchanger (Figure 6–5B). This membrane protein is not an ATPase but a different type of molecule called a *cotransporter*. Cotransporters move one type of ion against its electrochemical gradient by using the energy stored in the electrochemical gradient of a second ion. (The E. coli CIC protein discussed in Chapter 5 is a type of cotransporter.) In the case of the Na⁺-Ca²⁺ exchanger, the electrochemical gradient of Na⁺ drives the efflux of Ca²⁺. The exchanger transports three or four Na+ ions into the cell (down the electrochemical gradient for Na+) for each Ca2+ ion it removes (against the electrochemical gradient of Ca²⁺). Because Na⁺ and Ca²⁺ are transported in opposite directions, the exchanger is termed an antiporter. Ultimately, it is the hydrolysis of ATP by the Na⁺-K⁺ pump that provides the energy (stored in the Na⁺ gradient) to maintain the function of the Na⁺-Ca²⁺ exchanger. For this reason, ion flux driven by cotransporters is often referred to as secondary active transport, to distinguish it from the primary active transport driven directly by ATPases.

Chloride Ions Are Also Actively Transported

So far, for simplicity, we have ignored the contribution of chloride (Cl $^-$) to the resting potential. However, in most nerve cells the Cl $^-$ gradient is controlled by one or more active transport mechanisms so that $E_{\rm Cl}$ will differ from $V_{\rm r}$. As a result, the opening of Cl $^-$ channels will bias the membrane potential toward its Nernst potential. Chloride transporters typically use the energy stored in the gradients of other ions—they are cotransporters.

Cell membranes contain a number of different types of Cl⁻ cotransporters (Figure 6–5B). Some transporters increase intracellular Cl⁻ to levels greater than those that would be passively reached if the Cl⁻ Nernst potential was equal to the resting potential. In such cells $E_{\rm Cl}$ is positive to $V_{\rm r}$ so that the opening of Cl⁻ channels depolarizes the membrane. An example of this type of transporter is the Na⁺-K⁺-Cl⁻ cotransporter. This protein transports two Cl⁻ ions into the cell together with one Na⁺ and one K⁺ ion. As a result, the transporter is electroneutral. The Na⁺-K⁺-Cl⁻ cotransporter differs from the Na⁺-Ca²⁺ exchanger in that the former transports all three ions in the same direction—it is a *symporter*.

However, in most neurons the Cl^- gradient is determined by cotransporters that move Cl^- out of the cell. This action lowers the intracellular concentration of Cl^- so that E_{Cl} is typically more negative than the resting potential. As a result, the opening of Cl^- channels leads to an influx of Cl^- that hyperpolarizes the

membrane. The K⁺-Cl⁻ cotransporter is an example of such a transport mechanism; it moves one K⁺ ion out of the cell for each Cl⁻ ion it exports.

Interestingly, in early neuronal development cells tend to express primarily the Na⁺-K⁺-Cl⁻ cotransporter. At this stage the neurotransmitter γ-aminobutyric acid (GABA), which activates Cl⁻ channels, typically has an excitatory (depolarizing) effect. As neurons develop they begin to express the K⁺-Cl⁻ cotransporter, such that in mature neurons GABA typically hyperpolarizes the membrane and thus acts as an inhibitory neurotransmitter. In some pathological conditions in adults, such as certain types of epilepsy or chronic pain syndromes, the expression pattern of the Cl⁻ cotransporters may revert to that of the immature nervous system. This will lead to aberrant depolarizing responses to GABA that can produce abnormally high levels of excitation.

The Balance of Ion Fluxes That Maintains the Resting Membrane Potential Is Abolished During the Action Potential

In the nerve cell at rest the steady Na⁺ influx is balanced by a steady K⁺ efflux, so that the membrane potential is constant. However, this balance changes when the membrane is depolarized toward the threshold for an action potential. As the membrane potential approaches this threshold, voltage-gated Na⁺ channels open rapidly. The resultant increase in membrane conductance to Na⁺ causes the Na⁺ influx to exceed the K⁺ efflux once threshold is exceeded, creating a net influx of positive charge that causes further depolarization. The increase in depolarization causes still more voltage-gated Na⁺ channels to open, resulting in a greater influx of Na⁺, which accelerates the depolarization even further.

This regenerative, positive feedback cycle develops explosively, driving the membrane potential toward the Na⁺ equilibrium potential of +55 mV:

$$E_{\text{Na}} = \frac{RT}{F} \ln \frac{[\text{Na}]_{\text{o}}}{[\text{Na}]_{\text{i}}} = 58 \text{ mV } \log \frac{[440]}{[50]} = +55 \text{ mV}.$$

However, the membrane potential never quite reaches $E_{\rm Na}$ because K⁺ efflux continues throughout the depolarization. A slight influx of Cl⁻ into the cell also counteracts the depolarizing effect of the Na⁺ influx. Nevertheless, so many voltage-gated Na⁺ channels open during the rising phase of the action potential that the cell membrane's Na⁺ conductance is much

greater than the conductance of either Cl⁻ or K⁺. Thus, at the peak of the action potential the membrane potential approaches the Na⁺ equilibrium potential, just as at rest (when permeability to K⁺ is predominant) the membrane potential tends to approach the K⁺ equilibrium potential.

The membrane potential would remain at this large positive value near the Na⁺ equilibrium potential indefinitely but for two processes that repolarize the membrane, thus terminating the action potential. First, following the peak of the action potential the voltage-gated Na⁺ channels gradually close by the process of inactivation (see Chapters 5 and 7). Second, opening of the voltage-gated K⁺ channels causes the K⁺ efflux to gradually increase. The increase in K⁺ conductance is slower than the increase in Na⁺ conductance because of the slower rate of opening of the voltage-gated K⁺ channels. The slow increase in K⁺ efflux together with the decrease in Na⁺ influx produces a net efflux of positive charge from the cell, which continues until the cell has repolarized to its resting membrane potential.

The Contributions of Different Ions to the Resting Membrane Potential Can Be Quantified by the Goldman Equation

Although K⁺, Na⁺, and Cl⁻ fluxes set the value of the resting potential, $V_{\rm m}$ is not equal to $E_{\rm K}$, $E_{\rm Na}$, or $E_{\rm Cl}$ but lies at some intermediate value. As a general rule, when $V_{\rm m}$ is determined by two or more species of ions, the contribution of one species is determined not only by the concentrations of the ion inside and outside the cell but also by the ease with which the ion crosses the membrane. One convenient measure of how readily the ion crosses the membrane is the permeability (P)of the membrane to that ion, which has units of velocity (cm/s). This measure is similar to that of a diffusion constant, which determines the rate of solute movement in solution driven by a local concentration gradient. The dependence of membrane potential on ionic permeability and concentration is given by the Goldman equation:

$$V_{\rm m} = \frac{RT}{F} \ln \frac{P_{\rm K}[{\rm K}^+]_{\rm o} + P_{\rm Na}[{\rm Na}^+]_{\rm o} + P_{\rm Cl}[{\rm Cl}^-]_{\rm i}}{P_{\rm K}[{\rm K}^+]_{\rm i} + P_{\rm Na}[{\rm Na}^+]_{\rm i} + P_{\rm Cl}[{\rm Cl}^-]_{\rm o}}.$$

Goldman Equation

This equation applies only when $V_{\rm m}$ is not changing. It states that the greater the concentration of an ion species and the greater its membrane permeability, the greater its contribution to determining the membrane

potential. In the limit, when permeability to one ion is exceptionally high, the Goldman equation reduces to the Nernst equation for that ion. For example, if $P_{\rm K} >> P_{\rm CI}$ or $P_{\rm Na}$, as in glial cells, the equation becomes as follows:

$$V_{\rm m} \cong \frac{RT}{F} \ln \frac{[K^+]_{\rm o}}{[K^+]_{\rm i}}$$

Alan Hodgkin and Bernard Katz used the Goldman equation to analyze changes in membrane potential in the squid giant axon. They measured the variations in membrane potential in response to systematic changes in the extracellular concentrations of Na⁺, Cl⁻, and K⁺. They found that if $V_{\rm m}$ is measured shortly after the extracellular concentration is changed (before the internal ionic concentrations are altered), [K⁺]_o has a strong effect on the resting potential, [Cl⁻]_o has a moderate effect, and [Na⁺]_o has little effect. The data for the membrane at rest could be fit accurately by the Goldman equation using the following permeability ratios:

$$P_{\rm K}: P_{\rm Na}: P_{\rm Cl} = 1.0: 0.04: 0.45.$$

At the peak of the action potential there is an instant in time when $V_{\rm m}$ is not changing and the Goldman equation is applicable. At that point the variation of $V_{\rm m}$ with external ionic concentrations is fit best if a quite different set of permeability ratios is assumed:

$$P_{\rm K}: P_{\rm Na}: P_{\rm Cl} = 1.0:20:0.45.$$

For these values of permeability the Goldman equation approaches the Nernst equation for Na⁺:

$$V_{\rm m} \cong \frac{RT}{F} \ln \frac{[{\rm Na^+}]_{\rm o}}{[{\rm Na^+}]_{\rm i}} = +55 \,{\rm mV}.$$

Thus at the peak of the action potential, when the membrane is much more permeable to Na⁺ than to any other ion, $V_{\rm m}$ approaches $E_{\rm Na}$. However, the finite permeability of the membrane to K⁺ and Cl⁻ results in K⁺ efflux and Cl⁻ influx that partially counterbalance Na⁺ influx, thereby preventing $V_{\rm m}$ from quite reaching $E_{\rm Na}$.

The Functional Properties of the Neuron Can Be Represented as an Electrical Equivalent Circuit

The usefulness of the Goldman equation is limited because it cannot be used to determine how rapidly the membrane potential changes in response to a change in permeability. It is also inconvenient for determining the magnitude of the individual Na⁺, K⁺, and Cl⁻ currents.

This information can be obtained using a simple mathematical model derived from electrical circuits. The model, called an *equivalent circuit*, represents all of the important electrical properties of the neuron by a circuit consisting of conductors or resistors, batteries, and capacitors.¹

Equivalent circuits provide us with an intuitive understanding as well as a quantitative description of how current caused by the movement of ions generates signals in nerve cells.

The first step in developing an equivalent circuit is to relate the membrane's discrete physical properties to its electrical properties. We start by considering the lipid bilayer, which endows the membrane with electrical *capacitance*, the ability of an electrical nonconductor (insulator) to separate electrical charges on either side of it. The nonconducting phospholipid bilayer of the membrane separates the cytoplasm and extracellular fluid, both of which are highly conductive environments. The presence of a thin layer of opposing charges on the inside and outside surfaces of the cell membrane, acting as a capacitor, gives rise to the electrical potential difference across the membrane. The electrical potential difference or voltage across a capacitor is

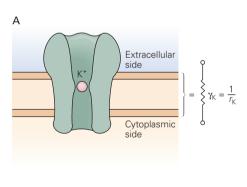

$$V = O/C$$
,

where Q is the net excess positive or negative charge on each side of the capacitor and C is the capacitance. Capacitance is measured in units of farads (F), and charge is measured in coulombs (where 96,500 coulombs of a univalent ion is equivalent to 1 mole of that ion). A charge separation of 1 coulomb across a capacitor of 1 F produces a potential difference of 1 volt. A typical value of membrane capacitance for a nerve cell is approximately 1 μF per cm² of membrane area. Very few charges are required to produce a large potential difference across such a capacitance. For example, the excess of positive and negative charges separated by the membrane of a spherical cell body with a diameter of 50 µm and a resting potential of -60 mV is 29×10^6 ions. Although this number may seem large, it represents only a tiny fraction (1/200,000) of the total number of positive or negative charges in solution within the cytoplasm. The bulk of the cytoplasm and the bulk of the extracellular fluid are electroneutral.

The membrane is a *leaky capacitor* because it is studded with ion channels that can conduct charge. Ion

channels endow the membrane with conductance and with the ability to generate electromotive force (emf). The lipid bilayer itself has effectively zero conductance or infinite resistance. However, because ion channels are highly conductive, they provide pathways of finite electrical resistance for ions to cross the membrane. Because neurons contain many types of channels selective for different ions, we must consider each class of ion channel separately.

In an equivalent circuit we can represent each K^+ channel as a resistor or conductor of ionic current with a single-channel conductance γ_K (remember, conductance = 1/resistance) (Figure 6–6). If there were no K^+ concentration gradient, the current through a single K^+ channel would be given by Ohm's law: $i_K = \gamma_K \times V_m$. However, since there is normally a K^+ concentration gradient, there is also a chemical force driving K^+ across the membrane, represented in the equivalent circuit by a battery. (A source of electrical potential is called an *electromotive force* and an electromotive force generated by a difference in chemical potentials is called a battery.) The electromotive force of this battery is given by E_K , the Nernst potential for K^+ (Figure 6–7).

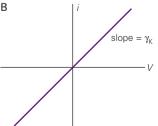

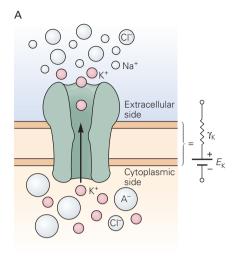

Figure 6–6 Electrical properties of a single K⁺ channel.

A. A single K^+ channel can be represented as a conductor or resistor (conductance, γ , is the inverse of resistance, r).

B. The relationship of current (i) and voltage (V) for a single K^+ channel in the absence of a concentration gradient. The slope of the line is equal to γ_k .

¹The electrical concepts underlying the equivalent circuit are described in detail in Appendix A.

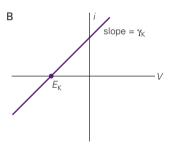

Figure 6–7 Chemical and electrical forces contribute to current through an ion channel.

A. A concentration gradient for K^+ gives rise to an electromotive force, which has a value equal to $E_{\rm K}$, the Nernst potential for K^+ . This can be represented by a battery. In this circuit the battery $E_{\rm K}$ is in series with the conductor $\gamma_{\rm K}$, representing the conductance of the K^+ channel.

B. The current-voltage relation for a K⁺ channel in the presence of both electrical and chemical driving forces. The potential at which the current is zero is equal to the K⁺ Nernst potential.

In the absence of voltage across the membrane, the normal K^+ concentration gradient causes an outward K^+ current. According to our convention for current, an outward movement of positive charge across the membrane corresponds to a positive current. According to the Nernst equation, when the concentration gradient for a positively charged ion, such as K^+ , is directed outward (ie, the K^+ concentration inside the cell is higher than outside), the equilibrium potential for that ion is negative. Thus the K^+ current that flows solely because of its concentration gradient is given by $i_K = -\gamma_K \times E_K$ (the negative sign is required because a negative equilibrium potential produces a positive current at 0 mV).

Finally, for a real neuron that has both a membrane voltage and a K⁺ concentration gradient, the net K⁺ current is given by the sum of the currents caused by the electrical and chemical driving forces:

$$i_{K} = (\gamma_{K} \times V_{m}) - (\gamma_{K} \times E_{K}) = \gamma_{K} \times (V_{m} - E_{K}).$$

The term $(V_{\rm m}-E_{\rm K})$ is called the *electrochemical driving force*. It determines the direction of ionic current and (along with the conductance) its magnitude. This equation is a modified form of Ohm's law that takes into account the fact that ionic current through a membrane is determined not only by the voltage across the membrane but also by the ionic concentration gradients.

A cell membrane has many resting K^+ channels, all of which can be combined into a single equivalent circuit consisting of a conductor in series with a battery (Figure 6–8). In this equivalent circuit the total conductance of all the K^+ channels (g_K), ie, the K^+ conductance of the cell membrane in its resting state, is equal to the number of resting K^+ channels (N_K) multiplied by the conductance of an individual K^+ channel (γ_K):

$$g_{\rm K} = N_{\rm K} \times \gamma_{\rm K}$$
.

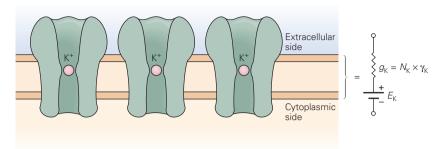

Because the battery in this equivalent circuit depends solely on the concentration gradient for K^+ and is independent of the number of K^+ channels, its value is the equilibrium potential for K^+ , E_K .

Like the population of resting K⁺ channels, all the resting Na⁺ channels can be represented by a single conductor in series with a single battery, as can the resting Cl⁻ channels (Figure 6–9). Because the K⁺, Na⁺, and Cl⁻ channels account for the bulk of the passive ionic current through the membrane in the cell at rest, we can calculate the resting potential by incorporating these three pathways into a simple equivalent circuit of a neuron.

To construct this circuit we need only connect the elements representing each type of channel at their two ends with elements representing the extracellular fluid and cytoplasm. The extracellular fluid and cytoplasm are both good conductors (compared with the membrane) because they have relatively large cross sectional areas and many ions available to carry charge. In a small region of a neuron, the extracellular and cytoplasmic resistances can be approximated by a *short circuit*—a conductor with zero resistance (Figure 6–10). The membrane capacitance ($C_{\rm m}$) is determined by the insulating properties of the lipid bilayer, which separates the extracellular and cytoplasmic conductors.

Figure 6–8 All the resting K⁺ channels in a nerve cell membrane can be lumped into a single equivalent circuit comprised of a battery in series with a conductor.

The K⁺ conductance of the membrane at rest is $g_{\rm K} = N_{\rm K} \times \gamma_{\rm K}$, where $N_{\rm K}$ is the number of passive K⁺ channels and $\gamma_{\rm K}$ is the conductance of a single K⁺ channel.

The equivalent circuit can be made more realistic by incorporating the active ion fluxes driven by the Na⁺-K⁺ pump, which extrudes three Na⁺ ions from the cell for every two K⁺ ions it pumps in. This electrogenic ATP-dependent pump, which keeps the ionic batteries charged, can be added to the equivalent circuit in the form of a current generator (Figure 6–11).

The use of the equivalent circuit to analyze neuronal properties quantitatively is illustrated in Box 6–2. There we see how the equivalent circuit can be used to calculate the resting potential, $V_{\rm m}$. We also see how the equivalent circuit can be simplified by combining all of the resting Na⁺, K⁺, and Cl⁻ channels into a single resting current pathway, with a conductance $g_{\rm r}$ and a battery $E_{\rm r}$, which is equal to the resting potential.

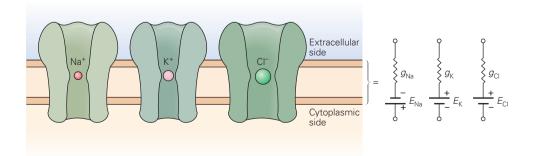

The Passive Electrical Properties of the Neuron Affect Electrical Signaling

Once an electrical signal is generated in part of a neuron, for example in response to a synaptic input on a branch of a dendrite, it is integrated with the other inputs to the neuron and then propagated to the axon initial segment, the site of action potential generation. During signaling, when a stimulus generates action potentials or local (synaptic or sensory generator) potentials in a neuron, the membrane potential changes frequently.

What determines the rate of change in potential with time or distance? What determines whether a stimulus will or will not produce an action potential? Here we consider the neuron's passive electrical properties and geometry and how these relatively constant properties affect the cell's electrical signaling. In the next five chapters we shall consider the properties of the gated channels and how the active ionic currents they control change the membrane potential.

Neurons have three passive electrical properties that are important for electrical signaling. We have already considered the resting membrane conductance or resistance ($g_r = 1/R_r$) and the membrane capacitance, C_m . A third important property that determines signal propagation along dendrites or axons is their intracellular axial resistance (r_a). Although, as mentioned above, the resistivity of cytoplasm is much lower than that of the membrane, the axial resistance along the entire length of an extended thin neuronal process can

Figure 6–9 The populations of Na⁺, K⁺, and Cl⁻ ion channels can each be represented by a battery in series with a conductor. The directions of the battery poles reflect the electromotive force generated by each ionic flux, inside negative for K⁺ and Cl⁻ and positive for Na⁺.

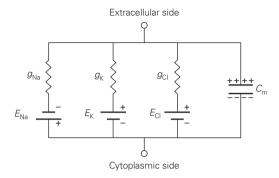

Figure 6–10 An equivalent circuit of the neuronal membrane. The elements of the circuit include pathways representing the Na⁺, K⁺, and Cl⁻ ion channels and short-circuit pathways provided by the cytoplasm and extracellular fluid. The lipid bilayer and the conducting solutions on its intracellular and extracellular surfaces endow the membrane with electrical capacitance (C_m).

be considerable. Because these three elements provide the return pathway to complete the electrical circuit when active ionic currents flow into or out of the cell, they determine the time course of the change in synaptic potential generated by the synaptic current. They also determine whether a synaptic potential generated in a dendrite will depolarize the trigger zone on the axon initial segment enough to fire an action potential. Finally, the passive properties influence the speed at which an action potential is conducted.

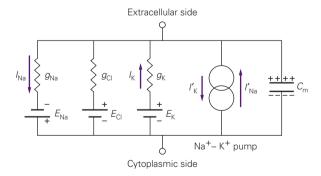

Figure 6–11 An equivalent circuit of passive and active current in a neuron. Under steady-state conditions the passive Na⁺ and K⁺ currents are balanced by active Na⁺ and K⁺ fluxes (I'_{Na} and I'_{K}) driven by the Na⁺-K⁺ pump. The active Na⁺ flux (I'_{Na}) is 50% greater than the active K⁺ flux (I'_{K}), and therefore I_{Na} is 50% greater than I_{K} , because the Na⁺-K⁺ pump transports three Na⁺ ions out for every two K⁺ ions it transports into the cell.

Membrane Capacitance Slows the Time Course of Electrical Signals

The steady-state change in a neuron's voltage in response to subthreshold current resembles the behavior of a simple resistor, but the initial *time course* of the change does not. A true resistor responds to a step change in current with a similar step change in voltage, but the neuron's membrane potential rises and decays more slowly than the step change in current (Figure 6–15). This property of the membrane is caused by its *capacitance*.

To understand how the capacitance slows down the voltage response, recall that the voltage across a capacitor is proportional to the charge stored on the capacitor. To alter the voltage, charge (*Q*) must be added to or removed from the capacitor (*C*):

$$\Delta V = \Delta O/C$$
.

To change the charge across the capacitor (the neuron's lipid bilayer), current must flow across the capacitor (I_c). Since current is the flow of charge per unit time ($I_c = \Delta Q/\Delta t$), the change in voltage across a capacitor is a function of the magnitude of the current and the time that the current flows:

$$\Delta V = I_c \cdot \Delta t/C$$
.

Thus the magnitude of the change in voltage across a capacitor in response to a current pulse depends on the duration of the current, because time is required to deposit and remove charge across the capacitor.

If the membrane had only resistive properties, a step pulse of outward current would change the membrane potential instantaneously. Conversely, if the membrane had only capacitive properties, the membrane potential would change linearly with time in response to the same step of current. Because the membrane has both capacitive and resistive properties in parallel, the actual change in membrane potential combines features of the two pure responses. The initial slope of the relation between $V_{\rm m}$ and time reflects a purely capacitive element, whereas the final slope and amplitude reflect a purely resistive element (Figure 6–15, upper plot).

In the simple case of the spherical cell body of a neuron, the time course of the potential change is described by the following equation:

$$\Delta V_{\rm m}(t) = I_{\rm m} R_{\rm m} (1 - e^{-t/\tau}),$$

where e is the base of the system of natural logarithms and has a value of approximately 2.72, and τ is the *membrane time constant*, given by the product of the

Box 6-2 Using the Equivalent Circuit Model to Calculate Resting Membrane Potential

An equivalent circuit model of the resting membrane can be used to calculate the resting potential. To simplify the calculation we shall initially ignore Cl⁻ channels and begin with just two types of resting channels, K⁺ and Na⁺, as illustrated in Figure 6–12. Moreover, we ignore the electrogenic influence of the Na⁺-K⁺ pump because it is small.

Because we consider only steady-state conditions, where the membrane potential, $V_{\rm m}$, is not changing, we can also ignore membrane capacitance. (Membrane capacitance and its delaying effect on changes in $V_{\rm m}$ are discussed below.)

Because there are more resting channels for K⁺ than for Na⁺, the membrane conductance for K⁺ is much greater than that for Na⁺. In the equivalent circuit in Figure 6–12, $g_{\rm K}$ (10 × 10⁻⁶ S) is 20 times higher than $g_{\rm Na}$ (0.5 × 10⁻⁶ S). Given these values and the values of $E_{\rm K}$ and $E_{\rm Na}$, $V_{\rm m}$ is calculated as follows.

Under the above conditions where the membrane potential is constant, there is no net current across the membrane. Therefore I_{Na} is equal and opposite to I_{K} :

$$-I_{\text{Na}} = I_K$$

or

$$I_{\text{Na}} + I_{\text{K}} = 0.$$
 (6–1)

We can easily calculate $I_{\rm Na}$ and $I_{\rm K}$ in two steps. First, we add up the separate potential differences across the Na⁺ and K⁺ branches of the circuit. Going from the inside to the outside across the Na⁺ branch, the total potential difference is the sum of the potential differences across $E_{\rm Na}$ and across $g_{\rm Na}$:*

$$V_{\rm m} = E_{\rm Na} + I_{\rm Na}/g_{\rm Na}$$
.

Similarly, for the K⁺ conductance branch

$$V_{\rm m} = E_{\rm K} + I_{\rm K}/g_{\rm K}$$
.

Next, we rearrange and solve for *I*:

$$I_{\text{Na}} = g_{\text{Na}} \times (V_{\text{m}} - E_{\text{Na}})$$
 (6–2a)

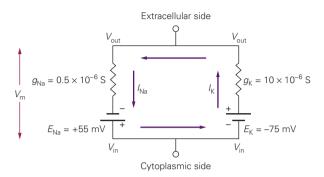

Figure 6–12 In this simple electrical equivalent circuit the resting membrane potential depends on the resting K⁺ and Na⁺ channels only.

$$I_{\rm K} = g_{\rm K} \times (V_{\rm m} - E_{\rm K}).$$
 (6–2b)

As these equations illustrate, the ionic current through each conductance branch is equal to the conductance of that branch multiplied by the net electrical driving force. For example, with the K⁺ current the conductance is proportional to the number of open K⁺ channels, and the driving force is equal to the difference between $V_{\rm m}$ and $E_{\rm K}$. If $V_{\rm m}$ is more positive than $E_{\rm K}$ (–75 mV), the driving force is positive and the current is outward; if $V_{\rm m}$ is more negative than $E_{\rm K}$, the driving force is negative and the current is inward.

Similar equations are used in a variety of contexts in this book to relate the magnitude of a particular ionic current to its membrane conductance and driving force.

As we saw in Equation 6–1, $I_{\text{Na}} + I_{\text{K}} = 0$. If we now substitute Equations 6–2a and 6–2b for I_{Na} and I_{K} in Equation 6–1, multiply through, and rearrange, we obtain the following expression:

$$V_{\rm m} \times (g_{\rm Na} + g_{\rm K}) = (E_{\rm Na} \times g_{\rm Na}) + (E_{\rm K} \times g_{\rm K}).$$

Solving for $V_{\rm m}$ we obtain an equation for the resting membrane potential that is expressed in terms of membrane conductances and batteries:

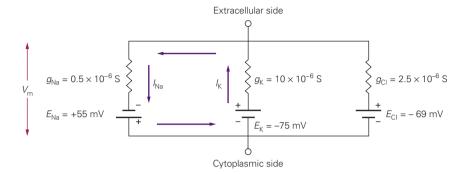

$$V_{\rm m} = \frac{(E_{\rm Na} \times g_{\rm Na}) + (E_{\rm K} \times g_{\rm K})}{g_{\rm Na} + g_{\rm K}}$$
 (6-3)

From this equation, using the values in our equivalent circuit (Figure 6–12), we calculate $V_{\rm m}$ = -69 mV.

Equation 6–3 states that $V_{\rm m}$ approaches the value of the ionic battery that has the greater conductance. This principle can be illustrated by considering what happens during the action potential. At the peak of the

^{*}Because we have defined $V_{\rm m}$ as $V_{\rm in}-V_{\rm out}$ the following convention must be used for these equations. Outward current (in this case $I_{\rm K}$) is positive and inward current is negative. Batteries whose positive pole is directed toward the inside of the membrane (eg, $E_{\rm Na}$) are given positive values in the equations. The reverse is true for batteries whose negative pole is directed toward the inside, such as the K+ battery.

Figure 6–13 This electrical equivalent circuit includes the Cl⁻ pathway. There is no current through the Cl⁻ channels because $V_{\rm m}$ is at $E_{\rm Cl}$.

action potential $g_{\rm K}$ is essentially unchanged from its resting value, but $g_{\rm Na}$ increases as much as 500-fold. This increase in $g_{\rm Na}$ is caused by the opening of voltage-gated Na⁺ channels. In the equivalent circuit in Figure 6–12, a 500-fold increase would change $g_{\rm Na}$ from 0.5×10^{-6} S to 250×10^{-6} S.

If we substitute this new value of $g_{\rm Na}$ into Equation 6–3 and solve for $V_{\rm m}$, we obtain +50 mV. $V_{\rm m}$ is closer to $E_{\rm Na}$ than to $E_{\rm K}$ at the peak of the action potential because $g_{\rm Na}$ is now 25-fold greater than $g_{\rm K}$, so that the Na⁺ battery becomes much more important than the K⁺ battery in determining $V_{\rm m}$.

The real resting membrane has open channels for Cl^- as well as for Na^+ and K^+ . One can derive a more general equation for V_m , following the steps outlined above, from an equivalent circuit that includes a conductance pathway for Cl^- with its associated Nernst battery (Figure 6–13):

$$V_{\rm m} = \frac{(E_{\rm Na} \times g_{\rm Na}) + (E_{\rm K} \times g_{\rm K}) + (E_{\rm Cl} \times g_{\rm Cl})}{g_{\rm Na} + g_{\rm K} + g_{\rm Cl}}.$$
 (6-4)

This equation is similar to the Goldman equation in that the contribution to $V_{\rm m}$ of each ionic battery is weighted in proportion to the conductance of the membrane for that particular ion. In the limit, if the conductance for one ion is much greater than that for the other ions, $V_{\rm m}$ approaches the value of that ion's Nernst potential.

The contribution of Cl⁻ ions to the resting potential can now be determined by comparing $V_{\rm m}$ calculated for the Na⁺ and K⁺ circuits only (Figure 6–12) and for all three ions (Figure 6–13). For most nerve cells the value of $g_{\rm Cl}$ ranges from one-fourth to one-half of $g_{\rm K}$. In the simplified example in Figure 6–13 Cl⁻ ions flow passively across the membrane, so that $E_{\rm Cl}$ is equal to the value of $V_{\rm m}$, which is determined by Na⁺ and K⁺.

Because $E_{\rm Cl} = V_{\rm m}$ (-69 mV in this case), there is no current through the Cl⁻ channels. As a result when we

include $g_{\rm Cl}$ and $E_{\rm Cl}$ in the circuit (Figure 6–13), the calculated value of $V_{\rm m}$ does not differ from that when the Cl-conductance is absent (Figure 6–12). However, in most neurons Cl⁻ is actively transported out of the cell so that $E_{\rm Cl}$ is more negative than the resting potential. Adding the Cl⁻ pathway to the calculation would shift $V_{\rm m}$ to a slightly more negative value.

The equivalent circuit can be further simplified by lumping the conductance of all the resting channels that contribute to the resting potential into a single conductance, g_r , and replacing the battery for each conductance channel with a single battery whose value, E_r , is given by Equation 6–4 (Figure 6–14). Here the subscript r stands for the resting channel pathway. Because the resting channels provide a pathway for the steady leakage of ions across the membrane, they are sometimes referred to as *leakage channels* (see Chapter 7). This consolidation of resting pathways will prove useful when we consider the effects on membrane voltage of current through voltage-gated and ligand-gated channels in later chapters.

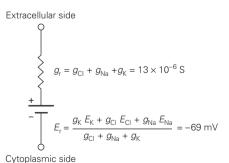

Figure 6–14 The Na⁺, K⁺, and Cl⁻ resting channels can be represented together by a single conductance and battery. The total resting membrane conductance (g_r) and the electromotive force or battery (E_r) give the resting potential determined by Equation 6–4.

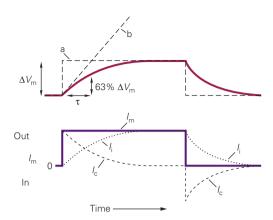

Figure 6–15 The rate of change in the membrane potential is slowed by the membrane capacitance. The upper plot shows the response of the membrane potential (ΔV_m) to a step current pulse (I_m) . The shape of the actual voltage response (red line) combines the properties of a purely resistive element (dashed line a) and a purely capacitive element (dashed line b). The time taken to reach 63% of the final voltage defines the membrane time constant, τ . The lower plot shows the two elements of the total membrane current (I_m) during the current pulse: the ionic current (I_l) across the resistive elements of the membrane (ion channels) and the capacitive current (I_c) .

membrane resistance and capacitance ($R_{\rm m}C_{\rm m}$). The time constant can be measured experimentally as the time it takes the membrane potential to rise to 1-1/e, or approximately 63% of its steady-state value (Figure 6–15, upper plot). Typical values of τ for neurons range from 20 to 50 ms. We shall return to the time constant in Chapter 10 where we consider the temporal summation of synaptic inputs in a cell.

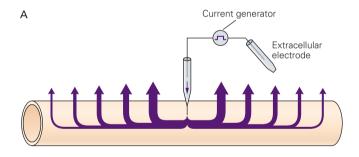

Membrane and Axoplasmic Resistance Affect the Efficiency of Signal Conduction

So far we have considered the effects of the passive properties of neurons on signaling only within the cell body. Distance is not a factor in the propagation of a signal in the neuron's soma because the cell body can be approximated as a tiny sphere whose membrane voltage is uniform. However, a subthreshold voltage signal traveling along extended structures such as dendrites, axons, and muscle fibers decreases in amplitude with distance from the site of initiation. To understand how this attenuation occurs, we will consider how the geometry of a neuron influences the distribution of current.

If current is injected into a dendrite at one point, how will the membrane potential change along the length of the dendrite? For simplicity, consider how membrane potential varies with distance after a constant-amplitude current pulse has been on for some time ($t \gg \tau$). Under these conditions the membrane capacitance is fully charged, so membrane potential reaches a steady value. The variation of the potential with distance thus depends solely on the relative values of the *membrane resistance* in a unit length of dendrite, $r_{\rm m}$ (units of $\Omega \cdot {\rm cm}$), and the *axial resistance* per unit length of dendrite, $r_{\rm a}$ (units of $\Omega/{\rm cm}$). The change in membrane potential becomes smaller with distance along the dendrite away from the current electrode (Figure 6–16A). This decay with distance is exponential and expressed by

$$\Delta V(x) = \Delta V_0 e^{-x/\lambda},$$

where λ is the membrane *length constant*, x is the distance from the site of current injection, and ΔV_0 is the change in membrane potential produced by the current at the site of injection (x = 0). The length

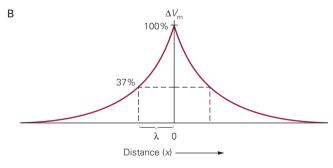

Figure 6–16 The change in membrane potential along a neuronal process during electrotonic conduction decreases with distance.

A. Current injected into a neuronal process by a microelectrode follows the path of least resistance to the return electrode in the extracellular fluid. (The thickness of the arrows represents the magnitude of membrane current.)

B. The change in $V_{\rm m}$ decays exponentially with distance from the site of current injection. The distance at which $\Delta V_{\rm m}$ has decayed to 37% of its value at the point of current injection defines the length constant, λ .

constant is the distance along the dendrite to the site where $\Delta V_{\rm m}$ has decayed to 1/e, or 37% of its initial value (Figure 6–16B). It is a measure of the efficiency of electrotonic conduction, the passive spread of voltage changes along the neuron, and is determined by the values of membrane and axial resistance as follows:

$$\lambda = \sqrt{(r_{\rm m}/r_{\rm a})}$$
.

The better the insulation of the membrane (that is, the greater $r_{\rm m}$) and the better the conducting properties of the inner core (the lower $r_{\rm a}$), the greater the length constant of the dendrite. That is because current is able to spread farther along the inner conductive core of the dendrite before leaking across the membrane at some point x to alter the local membrane potential:

$$\Delta V(x) = i(x) \cdot r_{\rm m}$$
.

The length constant is also a function of the diameter of the neuronal process. Neuronal processes vary greatly in diameter, from as much as 1 mm for the squid giant axon to 1 μ m for fine dendritic branches in the mammalian brain. For neuronal processes with similar ion channel densities (number of channels per unit membrane area) and cytoplasmic composition, the larger the diameter, the longer the length constant. Thus thicker axons and dendrites have longer length constants than do narrower processes and hence can transmit passive electrical signals for greater distances. Typical values for neuronal length constants range from 0.1 to 1.0 mm.

To understand how the diameter affects the length constant, we must consider how the diameter (or radius) of a process affects $r_{\rm m}$ and $r_{\rm a}$. Both $r_{\rm m}$ and $r_{\rm a}$ are measures of resistance for a unit length of a neuronal process of a given radius. The axial resistance $r_{\rm a}$ of the process depends inversely on the number of charge carriers (ions) in a cross section of the process. Therefore, given a fixed cytoplasmic ion concentration, r_a depends inversely on the cross sectional area of the process, $1/(\pi \cdot \text{radius}^2)$. The resistance of a unit length of membrane r_m depends inversely on the total number of channels in a unit length of the neuronal process. Channel density, the number of channels per µm² of membrane, is often similar among different-sized processes. As a result, the number of channels per unit length of a neuronal process increases in direct proportion to increases in membrane area, which depends on the circumference of the process times its length; therefore, $r_{\rm m}$ varies as $1/(2 \cdot \pi \cdot {\rm radius})$. Because $r_{\rm m}/r_{\rm a}$ varies in direct proportion to the radius of the process, the length constant is proportional to the square root of the radius.

The efficiency of electrotonic conduction has two important effects on neuronal function. First, it influences spatial summation, the process by which synaptic potentials generated in different regions of the neuron are added together at the trigger zone at the axon hillock (see Chapter 10). Second, electrotonic conduction is a factor in the propagation of the action potential. Once the membrane at any point along an axon has been depolarized beyond threshold, an action potential is generated in that region. This local depolarization spreads passively down the axon, causing successive adjacent regions of the membrane to reach the threshold for generating an action potential (Figure 6–17). Thus the depolarization spreads along the length of the axon by local current driven by the difference in potential between the active and resting regions of the axon membrane. In axons with longer length constants local current spreads a greater distance down the axon, and therefore the action potential propagates more rapidly.

Large Axons Are More Easily Excited Than Small Axons

The influence of axonal geometry on action potential conduction plays an important role in a common neurological exam. In the examination of a patient for diseases of peripheral nerves, the nerve often is stimulated by passing current between a pair of external cutaneous electrodes placed over the nerve, and the population of resulting action potentials (the *compound action potential*) is recorded farther along the nerve by a second pair of cutaneous voltage-recording electrodes. In this situation the total number of axons that generate action potentials varies with the amplitude of the current pulse.

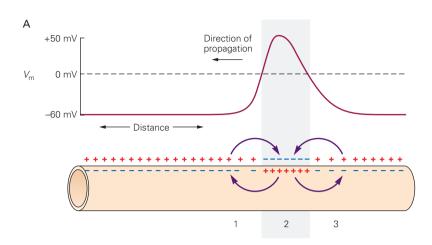

To drive a cell to threshold, a stimulating current from the positive electrode must pass through the cell membrane into the axon. There it travels along the axoplasmic core, eventually exiting the axon into the extracellular fluid through the membrane to reach the second (negative) electrode. However, most of the stimulating current does not even enter the axon, moving instead through neighboring axons or through the low-resistance pathway of the extracellular fluid. Thus, the axons into which current enters most easily are the most excitable.

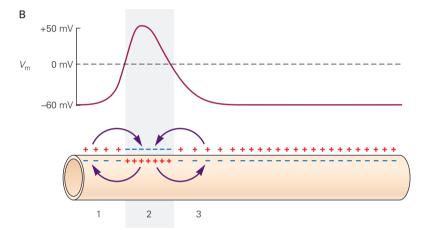

In general, axons with the largest diameter have the lowest threshold for excitation. The greater the diameter of the axon, the lower the axial resistance to the flow of current down the axon because the number of charge carriers (ions) per unit length of the axon is greater. Because more current enters the larger axon, the axon is depolarized more efficiently than a smaller

Figure 6–17 Electrotonic conduction contributes to propagation of the action potential.

A. An action potential propagating from right to left causes a difference in membrane potential in two adjacent regions of the axon. The difference creates a local-circuit current that causes the depolarization to spread passively. Current spreads from the more positive active region (2) to the less positive resting region ahead of the action potential (1), as well as to the less positive area behind the action potential (3). However, because there is also an increase in membrane K+ conductance in the wake of the action potential (see Chapter 7), the buildup of positive charge along the inner side of the membrane in area 3 is more than balanced by the local efflux of K+, allowing this region of membrane to repolarize.

B. A short time later, the action potential has traveled down the axon and the process can be repeated.

axon. For these reasons, larger axons are recruited at low values of current; axons with smaller diameter are recruited only at relatively greater current strengths.

The fact that larger axons conduct more rapidly and have a lower current threshold for excitation aids in the interpretation of clinical nerve-stimulation tests. Neurons that convey different types of information (eg, motor versus sensory) often differ in axon diameter and thus conduction velocity (see Table 22–1). In addition, a specific disease process may preferentially affect a subset of the functional classes of axons. Thus, using conduction velocity as a criterion to determine which classes of axons have defective conduction properties can help one infer the neuronal basis for the neurological deficit.

Passive Membrane Properties and Axon Diameter Affect the Velocity of Action Potential Propagation

The passive spread of depolarization during conduction of the action potential is not instantaneous. In fact,

electrotonic conduction is a rate-limiting factor in the propagation of the action potential. We can understand this limitation by considering a simplified equivalent circuit of two adjacent segments of axon membrane connected by a segment of axoplasm.

An action potential generated in one segment of membrane supplies depolarizing current to the adjacent membrane, causing it to depolarize gradually toward threshold (see Figure 6–17). According to Ohm's law, the larger the axoplasmic resistance, the smaller the current between adjacent membrane segments (I = V/R) and thus the longer it takes to change the charge on the membrane of the adjacent segment.

Recall that, since $\Delta V = \Delta Q/C$, the membrane potential changes slowly if the current is small because ΔQ , equal to current multiplied by time, changes slowly. Similarly, the larger the membrane capacitance, the more charge must be deposited on the membrane to change the potential across the membrane, so the current must flow for a longer time to produce a

given depolarization. Therefore, the time it takes for depolarization to spread along the axon is determined by both the axial resistance $r_{\rm a}$ and the capacitance per unit length of the axon $c_{\rm m}$ (units F/cm). The rate of passive spread varies inversely with the product $r_{\rm a}c_{\rm m}$. If this product is reduced, the rate of passive spread increases and the action potential propagates faster.

Rapid propagation of the action potential is functionally important, and two adaptive strategies have evolved to increase it. One is an increase in the diameter of the axon core. Because $r_{\rm a}$ decreases in proportion to the square of axon diameter, whereas $c_{\rm m}$ increases in direct proportion to diameter, the net effect of an increase in diameter is a decrease in $r_{\rm a}c_{\rm m}$. This adaptation has been carried to an extreme in the giant axon of the squid, which can reach a diameter of 1 mm. No larger axons have evolved, presumably because of the competing need to keep neuronal size small so that many cells can be packed into a limited space.

The second strategy to increase conduction velocity is the wrapping of a myelin sheath around an axon (see Chapter 4). This process is functionally equivalent to increasing the thickness of the axonal membrane by as much as 100 times. Because the capacitance of a parallel-plate capacitor such as the membrane is inversely proportional to the thickness of the insulation material (see Appendix A), myelination decreases $c_{\rm m}$ and thus $r_{\rm a}c_{\rm m}$. Myelination results in a proportionately much greater decrease in $r_{\rm a}c_{\rm m}$ than does the same increase in the diameter of the axon core because the many layers of membrane wrapped in the myelin sheath produce a very large decrease in $c_{\rm m}$. For this reason, conduction in myelinated axons is faster than in nonmyelinated axons of the same diameter.

In a neuron with a myelinated axon the action potential is triggered at the nonmyelinated initial segment of membrane just distal to the axon hillock. The inward current that flows through this region of membrane is available to discharge the capacitance of the myelinated axon ahead of it. Even though the capacitance of the axon is quite small (because of the myelin insulation), the amount of current down the core of the axon from the trigger zone is not enough to discharge the capacitance along the *entire* length of the myelinated axon.

To prevent the action potential from dying out, the myelin sheath is interrupted every 1 to 2 mm by bare patches of axon membrane approximately 1 μm in length, the nodes of Ranvier (see Chapter 4). Although the area of membrane at each node is quite small, the nodal membrane is rich in voltage-gated Na $^+$ channels and thus can generate an intense depolarizing inward Na $^+$ current in response to the passive spread

of depolarization down the axon. These regularly distributed nodes thus boost the amplitude of the action potential periodically, preventing it from decaying with distance.

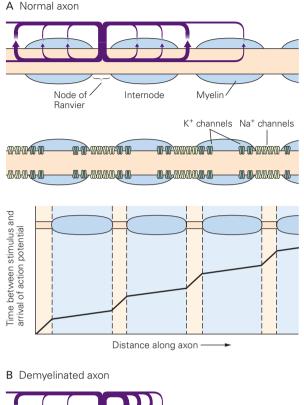

The action potential, which spreads quite rapidly along the internode because of the low capacitance of the myelin sheath, slows down as it crosses the high-capacitance region of each bare node. Consequently, as the action potential moves down the axon it jumps quickly from node to node (Figure 6–18A). For this reason, the action potential in a myelinated axon is said to move by *saltatory conduction* (from the Latin *saltare*, to jump). Because ionic membrane current flows only at the nodes in myelinated fibers, saltatory conduction is also favorable from a metabolic standpoint. Less energy must be expended by the Na⁺-K⁺ pump in restoring the Na⁺ and K⁺ concentration gradients, which tend to run down as the action potential is propagated.

Various diseases of the nervous system are caused by demyelination, such as multiple sclerosis and Guillain-Barré syndrome. As an action potential goes from a myelinated region to a bare stretch of demyelinated axon, it encounters a region of relatively high $c_{
m m}$ and low $r_{\rm m}$. The inward current generated at the node just before the demyelinated segment may be too small to provide the capacitive current required to depolarize the segment of demyelinated membrane to threshold. In addition, this local-circuit current does not spread as far as it normally would because it is flowing into a segment of axon that has a short length constant because of its low $r_{\rm m}$ (Figure 6–18B). These two factors can combine to slow, and in some cases actually block, the conduction of action potentials, causing devastating effects on behavior (see Chapter 7).

An Overall View

The lipid bilayer, which is virtually impermeant to ions, is an insulator separating two conducting solutions, the cytoplasm and the extracellular fluid. Ions can cross the lipid bilayer only by passing through ion channels in the cell membrane. When the cell is at rest, passive ionic fluxes into and out of the cell are balanced, so the charge separation across the membrane remains constant and the membrane potential is maintained at its resting value.

The value of the resting membrane potential in nerve cells is determined primarily by resting channels that conduct K⁺, Cl⁻, and Na⁺. In general, the membrane potential is closest to the equilibrium (Nernst) potential of the ion (or ions) with the greatest membrane

Demyelinated region

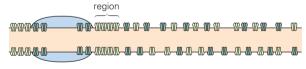

Figure 6–18 Action potentials in myelinated nerves are regenerated at the nodes of Ranvier.

A. The densities of capacitive and ionic membrane currents (membrane current per unit area of membrane) are much higher at the nodes of Ranvier than in the internodal regions. (In the figure the density of membrane current at any point along the axon is represented by the thickness of the arrows.) Because of the higher capacitance of the axon membrane at the nodes, the action potential slows down as it approaches each node and thus appears to skip rapidly from node to node as it propagates from left to right.

B. In regions of the axon that have lost their myelin, the spread of the action potential is slowed down or blocked. The local-circuit currents must discharge a larger membrane capacitance and, because of the shorter length constant (caused by the low membrane resistance in demyelinated stretches of axon), they do not spread well down the axon.

permeability. The permeability of a cell membrane for an ion species is proportional to the number of open channels that allow passage of that ion.

The resting membrane potential is close to the Nernst potential for K⁺, the ion to which the membrane is most permeable. The membrane is also somewhat permeable to Na⁺, however, and therefore an influx of Na⁺ shifts the membrane potential slightly positive to the K⁺ Nernst potential. At this potential the electrical and chemical driving forces acting on K⁺ are no longer in balance, so K⁺ diffuses out of the cell. The passive fluxes of K⁺ and Na⁺ are each counterbalanced by active fluxes driven by the Na⁺-K⁺ pump.

Chloride is actively transported out of most but not all neurons in the adult nervous system. When it is not, it is passively distributed so as to be at equilibrium inside and outside the cell. Under most physiological conditions the bulk concentrations of Na⁺, K⁺, and Cl⁻ inside and outside the cell are constant. Changes in membrane potential that generate neuronal signals (action potentials, synaptic potentials, and receptor potentials) are caused by substantial changes in the membrane's relative permeabilities to these three ions. These changes in permeability, caused by the opening of gated ion channels, change the net charge separation across the membrane, but produce only negligible changes in the bulk concentrations of ions.

Two competing requirements determine the functional design of neurons. First, to maximize the computing power of the nervous system, neurons must be small so that large numbers of them can fit into the brain and spinal cord. Second, to maximize the ability of the animal to respond to changes in its environment, neurons must conduct signals rapidly. These two adaptive features are constrained by the materials from which neurons are made.

Because the nerve cell membrane is thin and surrounded by two conducting media, it has a high capacitance. In addition, the currents that change the charge on the membrane capacitance along the length of an axon or dendrite flow through a relatively poor conductor—a thin column of cytoplasm. These two factors combine to slow down the conduction of voltage signals. Moreover, the various ion channels that are open at rest and that give rise to the resting potential also degrade the signaling function of the neuron, as they make the cell leaky and limit how far a signal can travel passively.

To compensate for these physical constraints neurons use voltage-gated channels to generate action potentials. The action potential is continually regenerated along the axon and thus conducted without

attenuation. For pathways in which rapid signaling is particularly important, conduction of the action potential is enhanced by either myelination of the axon or an increase in axon diameter, or by both.

signals over long distances because the long-distance signal, the action potential, is continually regenerated and thus does not attenuate as it moves down the axon. In Chapter 6 we saw how an action potential arises from sequential changes in the membrane's permeability to Na⁺ and K⁺ ions. We also considered how the membrane's passive properties influence the speed at which action potentials are conducted. In this chapter we focus on the voltage-gated ion channels that are critical for generating and propagating action potentials and consider how these channels are responsible for many important features of a neuron's electrical excitability.

Action potentials have four properties important for neuronal signaling. First, they have a threshold for initiation. As we saw in Chapter 6, in many nerve cells the membrane behaves as a simple resistor in response to small hyperpolarizing or depolarizing current steps. The membrane voltage changes in a graded manner as a function of the size of the current step according to Ohm's law, $\Delta V = \Delta I \cdot R$ (in terms of conductance, $\Delta V = \Delta I/G$). However, as the size of the depolarizing current increases, eventually a threshold voltage is reached, typically at around –50 mV, at which point an action potential is generated (see Figure 6–2C). Second, the action potential is an all-or-none event. The size and shape of an action potential initiated by

a large depolarizing current is the same as that of an action potential evoked by a current that just surpasses the threshold. Third, the action potential is conducted without decrement. It has a self-regenerative feature that keeps the amplitude constant, even when it is conducted over great distances. Fourth, the action potential is followed by a refractory period. For a brief time after an action potential is generated, the neuron's ability to fire a second action potential is suppressed. The refractory period limits the frequency at which a nerve can fire action potentials, and thus limits the information-carrying capacity of the axon.

These four properties of the action potential—initiation threshold, all-or-none nature, conduction without decrement, and refractory period—are unusual for biological processes, which typically respond in a graded fashion to changes in the environment. Biologists were puzzled by these properties for almost 100 years after the action potential was first measured in the mid 1800s. Finally, in the late 1940s and early 1950s studies of the membrane properties of the giant axon of the squid by Alan Hodgkin, Andrew Huxley, and Bernard Katz provided the first quantitative insight into the mechanisms underlying the action potential.

The Action Potential Is Generated by the Flow of Ions Through Voltage-Gated Channels

An important early insight into how action potentials are generated came from an experiment performed by Kenneth Cole and Howard Curtis. While recording from the giant axon of the squid they found that ion conductance across the membrane increases dramatically during the action potential (Figure 7–1). This discovery provided the first evidence that the action potential results from changes in the flux of ions through channels in the membrane. It also raised two central questions: Which ions are responsible for the action potential, and how is the conductance of the membrane regulated?

A key insight into this problem was provided by Alan Hodgkin and Bernard Katz, who found that the amplitude of the action potential is reduced when the external Na⁺ concentration is lowered, indicating that Na⁺ influx is responsible for the rising phase of

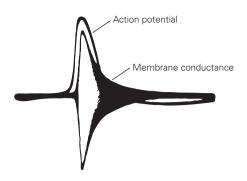

Figure 7–1 The action potential results from an increase in ionic conductance of the axon membrane. This historic recording from an experiment conducted in 1939 by Kenneth Cole and Howard Curtis shows the oscilloscope record of an action potential superimposed on a simultaneous record of membrane conductance.

the action potential. They proposed that depolarization of the cell above threshold causes a brief increase in the cell membrane's permeability to Na⁺, during which Na⁺ permeability overwhelms the dominant K⁺ permeability of the resting cell membrane, thereby driving the membrane potential towards $E_{\rm Na}$. Their data also suggested that the falling phase of the action potential was caused by a later increase in K⁺ permeability.

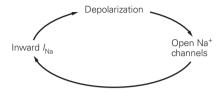

Sodium and Potassium Currents Through Voltage-Gated Channels Are Recorded with the Voltage Clamp

This insight of Hodgkin and Katz raised a further question. What mechanism is responsible for regulating the changes in the Na⁺ and K⁺ permeabilities of the membrane? Hodgkin and Andrew Huxley reasoned that the Na⁺ and K⁺ permeabilities were regulated directly by the membrane voltage. To test this hypothesis they systematically varied the membrane potential in the squid giant axon and measured the resulting changes in the conductance of voltage-gated Na⁺ and K⁺ channels. To do this they made use of a new apparatus, the voltage clamp, developed by Kenneth Cole.

Prior to the availability of the voltage-clamp technique, attempts to measure Na⁺ and K⁺ conductance as a function of membrane potential had been limited by the strong interdependence of the membrane potential and the gating of Na⁺ and K⁺ channels. For example, if the membrane is depolarized sufficiently to open some of the voltage-gated Na⁺ channels, the influx of Na⁺ through these channels causes further depolarization. The additional depolarization causes still more

¹The all-or-none property describes an action potential that is generated under a specific set of conditions. The size and shape of the action potential *can* be affected by changes in membrane properties, ion concentrations, temperature, and other variables, as discussed later in the chapter.

Na⁺ channels to open and consequently induces more inward Na⁺ current:

This positive feedback cycle, which eventually drives the membrane potential to the peak of the action potential, makes it impossible to achieve a stable membrane potential. A similar coupling between current

and membrane potential complicates the study of the voltage-gated K⁺ channels.

The voltage clamp interrupts the interaction between the membrane potential and the opening and closing of voltage-gated ion channels. It does so by adding or withdrawing a current from the axon that is equal to the current flowing through the voltage-gated membrane channels. In this way the voltage clamp prevents the membrane potential from changing. The amount of current that must be generated by the voltage clamp to keep the membrane potential constant provides a direct measure of the current flowing across the membrane (Box 7–1). Using the voltage-clamp

Box 7–1 Voltage-Clamp Technique

The voltage-clamp technique was developed by Kenneth Cole in 1949 to stabilize the membrane potential of neurons for experimental purposes. It was used by Alan Hodgkin and Andrew Huxley in the early 1950s in a series of experiments that revealed the ionic mechanisms underlying the action potential.

The voltage clamp permits the experimenter to "clamp" the membrane potential at predetermined levels, preventing changes in membrane current from influencing the membrane potential. By controlling the membrane potential one can measure the effect of changes in membrane potential on the membrane's conductance of individual ion species.

The voltage clamp consists of one intracellular and extracellular pair of electrodes used to measure the membrane potential and one intracellular and extracellular pair of electrodes used to pass current across the membrane (Figure 7–2). Through the use of a negative feedback amplifier, the voltage clamp is able to pass the correct amount of current across the cell membrane to rapidly step the membrane to a constant predetermined potential.

Depolarization opens voltage-gated Na⁺ and K⁺ channels, initiating movement of Na⁺ and K⁺ across the membrane. This change in membrane current ordinarily would change the membrane potential, but the voltage clamp maintains the membrane potential at a predetermined (commanded) level.

When Na⁺ channels open in response to a moderate depolarizing voltage step, an inward ionic current develops because Na⁺ ions are driven through these channels by their electrochemical driving force. This Na⁺ influx would normally depolarize the membrane by increasing the positive charge on the inside of the membrane and reducing the positive charge on the outside.

The voltage clamp intervenes in this process by simultaneously withdrawing positive charges from the cell and depositing them in the external solution. By generating a current that is equal and opposite to the ionic current through the membrane, the voltage-clamp circuit automatically prevents the ionic current from changing the membrane potential from the commanded value. As a result, the *net* amount of charge separated by the membrane does not change and therefore no significant change in $V_{\rm m}$ can occur.

The voltage clamp is a negative feedback system. A negative feedback system is one in which the value of the output of the system ($V_{\rm m}$ in this case) is fed back as the input to a system and compared to a reference value (the command signal). Any difference between the command signal and the output signal activates a "controller" (the feedback amplifier in this case) that automatically reduces the difference. Thus the actual membrane potential automatically and precisely follows the command potential.

For example, assume that an inward $\mathrm{Na^+}$ current through the voltage-gated $\mathrm{Na^+}$ channels ordinarily causes the membrane potential to become more positive than the command potential. The input to the feedback amplifier is equal to $(V_{\mathrm{command}} - V_{\mathrm{m}})$. The amplifier generates an output voltage equal to this error signal multiplied by the gain of the amplifier. Thus, both the input and the resulting output voltage at the feedback amplifier will be negative.

This negative output voltage will make the internal current electrode negative, withdrawing net positive charge from the cell through the voltage-clamp circuit. As the current flows around the circuit, an equal amount of net positive charge will be deposited into the external solution through the other current electrode.

A refinement of the voltage clamp, the patch-clamp technique, allows the functional properties of single ion channels to be analyzed (see Box 5–1).

technique, Hodgkin and Huxley provided the first complete description of the ionic mechanisms underlying the action potential.

One advantage of the voltage clamp is that it readily allows the ionic and capacitive components of membrane current to be analyzed separately. As described in Chapter 6, the membrane potential $V_{\rm m}$ is proportional to the charge $Q_{\rm m}$ on the membrane capacitance $C_{\rm m}$. When $V_{\rm m}$ is not changing, $Q_{\rm m}$ is constant, and no capacitive current ($\Delta Q_{\rm m}/\Delta t$) flows. Capacitive current flows *only* when $V_{\rm m}$ is changing. Therefore when the membrane potential changes in response to a very rapid step of command potential, capacitive current flows only at

the beginning and end of the step. Because the capacitive current is essentially instantaneous, the ionic currents that subsequently flow through the voltage-gated channels can be analyzed separately.

Measurements of these ionic currents can be used to calculate the voltage and time dependence of changes in membrane conductance caused by the opening and closing of Na⁺ and K⁺ channels. This information provides insights into the properties of these two types of channels.

A typical voltage-clamp experiment starts with the membrane potential clamped at its resting value. When a 10 mV depolarizing step is applied, a very brief outward current instantaneously discharges the

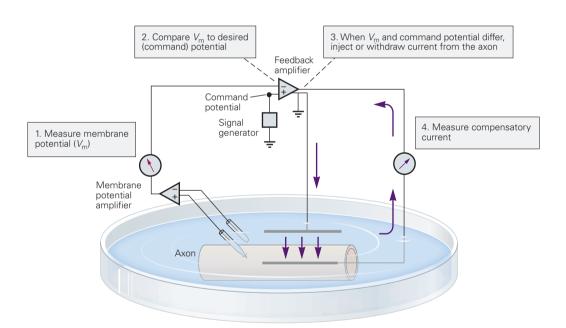

Figure 7–2 The negative feedback mechanism of the voltage clamp. Membrane potential (V_m) is measured by one amplifier connected to an intracellular electrode and an extracellular electrode in the bath. The membrane potential signal is displayed on an oscilloscope and is also fed into the negative terminal of the voltage-clamp feedback amplifier. The command potential, which is selected by the experimenter and can be of any desired amplitude and waveform, is fed into the positive terminal of the feedback amplifier. The feedback amplifier then subtracts the membrane potential from the command potential and amplifies any difference between these two signals. The voltage output of the amplifier is connected to the internal

current electrode, a thin wire that runs the length of the axon core. The negative feedback ensures that the voltage output of the amplifier drives a current across the resistance of the current electrode that alters the membrane voltage to minimize any difference between $V_{\rm m}$ and the command potential. To accurately measure the current-voltage relationship of the cell membrane, the membrane potential must be uniform along the entire surface of the axon. This is made possible by the highly conductive internal current electrode, which short-circuits the axoplasmic resistance, reducing axial resistance to zero (see Chapter 6). This low-resistance pathway eliminates all variations in electrical potential along the axon core.

membrane capacitance by the amount required for a 10 mV depolarization. This capacitive current (I_c) is followed by a smaller outward current that persists for the duration of the voltage step. This steady ionic current flows through the nongated resting ion channels of the membrane, which we refer to here as *leakage channels* (see Box 6–2). The current through these channels is called the *leakage current*, I_1 . The total conductance of this population of channels is called the *leakage conductance* (g_1). At the end of the step a brief inward capacitive current repolarizes the membrane to its initial voltage and the total membrane current returns to zero (Figure 7–3A).

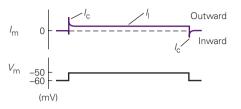

If a large depolarizing step is commanded, the current record is more complicated. The capacitive and leakage currents both increase in amplitude. In addition, shortly after the end of the capacitive current and the start of the leakage current, an inward (negative) current develops; it reaches a peak within a few milliseconds, declines, and gives way to an outward current. This outward current reaches a plateau that is maintained for the duration of the voltage step (Figure 7–3B).

A simple interpretation of these results is that the depolarizing voltage step sequentially turns on two types of voltage-gated channels that select for two distinct ions. One type of channel conducts ions that generate an inward current, while the other conducts ions that generate an outward current. Because these two oppositely directed currents partially overlap in time, the most difficult task in analyzing voltage-clamp experiments is to determine their separate time courses.

Hodgkin and Huxley achieved this separation by changing ions in the bathing solution. By replacing Na⁺ with a larger, impermeant cation (choline·H⁺), they eliminated the inward Na⁺ current. Later, the task of separating inward and outward currents was made easier by the discovery of drugs or toxins that selectively block the different classes of voltage-gated channels (Figure 7–4). Tetrodotoxin, a poison from a certain Pacific puffer fish, blocks the voltage-gated Na⁺ channel with a very high potency in the nanomolar range of concentration. (Ingestion of only a few milligrams of tetrodotoxin from improperly prepared puffer fish, consumed as the Japanese sushi delicacy *fugu*, can be fatal.) The cation tetraethylammonium specifically blocks the squid axon voltage-gated K⁺ channel.

When tetraethylammonium is applied to the axon to block the K^+ channels, the total membrane current $(I_{\rm m})$ consists of $I_{\rm c}$, $I_{\rm l}$, and $I_{\rm Na}$. The leakage conductance, $g_{\rm l}$, is constant; it does not vary with $V_{\rm m}$ or with time. Therefore the leakage current $I_{\rm l}$ can be readily calculated and subtracted from $I_{\rm m}$, leaving $I_{\rm Na}$ and $I_{\rm c}$. Because

A Currents from small depolarization

B Currents from large depolarization

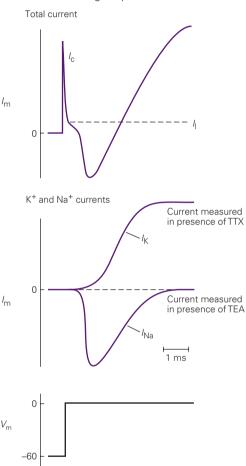

Figure 7–3 A voltage-clamp experiment demonstrates the sequential activation of two types of voltage-gated channels.

Time

(mV)

A. A small depolarization (10 mV) elicits capacitive and leakage currents (I_c and I_r , respectively), the components of the total membrane current (I_m).

B. A larger depolarization (60 mV) results in larger capacitive and leakage currents, plus a time-dependent inward ionic current followed by a time-dependent outward ionic current.

Top: Total (net) current in response to the depolarization. **Middle**: Individual Na⁺ and K⁺ currents. Depolarizing the cell in the presence of tetrodotoxin (TTX), which blocks the Na⁺ current, or in the presence of tetraethylammonium (TEA), which blocks the K⁺ current, reveals the pure K⁺ and Na⁺ currents ($I_{\rm K}$ and $I_{\rm Na}$, respectively) after subtracting $I_{\rm c}$ and $I_{\rm c}$. **Bottom**: Voltage step.

Figure 7–4 Drugs that block voltage-gated Na⁺ and K⁺ channels.

A. Tetrodotoxin and saxitoxin both bind to Na⁺ channels with a very high affinity. Tetrodotoxin is produced by certain puffer fish, newts, and frogs. Saxitoxin is synthesized by the dinoflagellates *Gonyaulax*, which are responsible for red tides. Consumption of clams or other shellfish that have fed on the dinoflagellates during a red tide causes paralytic shellfish poisoning.

B. Tetraethylammonium is a cation that blocks certain voltage-gated K^+ channels with a relatively low affinity. The plus signs represent positive charge. 4-Aminopyridine is another blocker of K^+ channels. It is used to improve conduction of nerve impulses in patients with multiple sclerosis.

 $I_{\rm c}$ occurs only briefly at the beginning and end of the pulse, it is easily isolated by visual inspection, revealing the pure $I_{\rm Na}$. Similarly, $I_{\rm K}$ can be measured when the Na⁺ channels are blocked by tetrodotoxin (Figure 7–3B).

By stepping the membrane to a wide range of potentials, Hodgkin and Huxley were able to measure the Na⁺ and K⁺ currents over the entire voltage extent of the action potential (Figure 7–5). They found that the Na⁺ and K⁺ currents vary as a graded function of the membrane potential. As the membrane voltage is made more positive, the outward K⁺ current becomes larger. The inward Na⁺ current also becomes larger with increases in depolarization, up to a certain extent. However, as the voltage becomes more and more positive, the Na⁺ current eventually declines in amplitude. When the membrane potential is +55 mV, the Na⁺ current is zero. Positive to +55 mV, the Na⁺ current reverses direction and becomes outward.

Hodgkin and Huxley explained this behavior by a very simple model in which the size of the Na⁺ and K⁺ currents is determined by two factors. The first is the magnitude of the Na⁺ or K⁺ conductance, g_{Na} or g_{K} , which reflects the number of Na⁺ or K⁺ channels open at any instant (see Chapter 6). The second factor is the electrochemical driving force on Na⁺ ions ($V_{\text{m}} - E_{\text{Na}}$) or K⁺ ions ($V_{\text{m}} - E_{\text{K}}$). The model is thus expressed as:

$$I_{\rm Na} = g_{\rm Na} \times (V_{\rm m} - E_{\rm Na})$$

$$I_{\rm K} = g_{\rm K} \times (V_{\rm m} - E_{\rm K}).$$

According to this model the amplitudes of $I_{\rm Na}$ and $I_{\rm K}$ change as the voltage is made more positive because there is an increase in $g_{\rm Na}$ and $g_{\rm K}$. The Na⁺ and K⁺

conductances increase because the opening of the Na⁺ and K⁺ channels is voltage-dependent. The currents also change in response to changes in the electrochemical driving forces.

Both I_{Na} and I_{K} initially increase in amplitude as the membrane is made more positive because g_{Na} and $g_{\rm K}$ increase steeply with voltage. However, as the membrane potential approaches E_{Na} (+55 mV), I_{Na} declines because of the decrease in inward driving force, even though g_{Na} is large. That is, the positive membrane voltage now opposes the influx of Na⁺ down its chemical concentration gradient. At +55 mV the chemical and electrical driving forces are in balance so there is no net I_{Na} , even though g_{Na} is quite large. As the membrane is made positive to E_{Na} , the driving force on Na^+ becomes positive. That is, the electrical driving force pushing Na⁺ out is now greater than the chemical driving force pulling Na^+ in, and hence I_{Na} becomes outward. The behavior of I_K is simpler; because E_K is quite negative (-75 mV), both g_K and the outward driving force on K^+ become larger as the membrane is made more positive, thereby increasing the outward K⁺ current.

Voltage-Gated Sodium and Potassium Conductances Are Calculated from Their Currents

From the two preceding equations Hodgkin and Huxley were able to calculate g_{Na} and g_{K} by dividing measured Na⁺ and K⁺ currents by the known Na⁺ and K⁺ electrochemical driving forces. Their results provide direct insight into how membrane voltage controls channel opening because the values of g_{Na} and g_{K} reflect the number of open Na⁺ and K⁺ channels (Box 7–2).

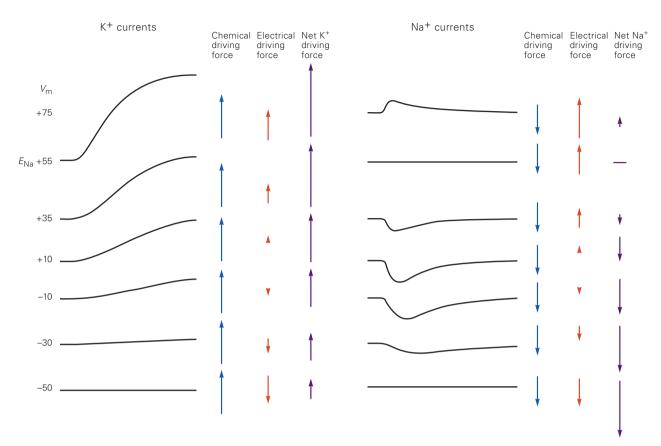

Figure 7–5 The magnitude and polarity of the Na⁺ and K⁺ membrane currents vary with the amplitude of membrane depolarization. Left: With progressive depolarization the voltage-clamped membrane K⁺ current increases monotonically, because both g_k and $(V_m - E_k)$, the driving force for K⁺, increase with increasing depolarization. The voltage during the depolarization is indicated at left. The direction and magnitude of the chemical (E_k) and electrical driving force on K⁺, as well as the net driving force, is given by arrows at the right of each trace. (Up arrows = outward force; down arrows = inward force.)

Right: At first the Na⁺ current becomes increasingly inward with increasing depolarization due to the increase in $g_{\rm Na}$. However, as the membrane potential approaches $E_{\rm Na}$ (+55 mV) the magnitude of the inward Na⁺ current begins to decrease due to the decrease in inward driving force ($V_{\rm m}-E_{\rm Na}$). Eventually, $I_{\rm Na}$ goes to zero when the membrane potential reaches $E_{\rm Na}$. At depolarizations positive to $E_{\rm Na}$, the sign of ($V_{\rm m}-E_{\rm Na}$) reverses, and $I_{\rm Na}$ becomes outward. Arrows at the right of each trace show chemical ($E_{\rm Na}$) and electrical driving forces and net Na⁺ driving force.

Measurements of $g_{\rm Na}$ and $g_{\rm K}$ at various levels of membrane potential reveal two functional similarities and two differences between the Na⁺ and K⁺ channels. Both types of channels open in response to depolarization. Also, as the size of the depolarization increases, the probability and rate of opening increase for both types of channels. The Na⁺ and K⁺ channels differ, however, in the rate at which they open and in their responses to prolonged depolarization. At all levels of depolarization the Na⁺ channels open more rapidly than K⁺ channels (Figure 7–7). When the depolarization is maintained for some time, the Na⁺ channels begin to close, leading to a decrease of inward current. The process by which Na⁺ channels close during a prolonged depolarization is termed *inactivation*.

Thus depolarization causes Na⁺ channels to switch between three different states—resting, activated, or inactivated—which represent three different conformations of the Na⁺ channel protein (see Figure 5–7). In contrast, squid axon K⁺ channels do not inactivate; they remain open as long as the membrane is depolarized, at least for voltage-clamp depolarizations lasting up to tens of milliseconds (Figure 7–7).

In the inactivated state the Na⁺ channel cannot be opened by further membrane depolarization. The inactivation can be reversed only by repolarizing the membrane to its negative resting potential, whereupon the channel switches to the resting state. This switch takes some time because channels leave the inactivated state relatively slowly (Figure 7–8).

Box 7-2 Calculation of Membrane Conductances from Voltage-Clamp Data

Membrane conductances can be calculated from voltage-clamp currents using equations derived from an equivalent circuit (Figure 7–6) that includes the membrane capacitance ($C_{\rm m}$); the leakage conductance ($g_{\rm l}$), representing the conductance of all of the resting (nongated) K⁺, Na⁺, and Cl⁻ channels (see Chapter 6); and $g_{\rm Na}$ and $g_{\rm K}$, the conductances of the voltage-gated Na⁺ and K⁺ channels.

In the equivalent circuit the ionic battery of the leakage channels, E_{ν} is equal to the resting membrane potential, and $g_{\rm Na}$ and $g_{\rm K}$ are in series with their appropriate ionic batteries.

The current through each class of voltage-gated channel may be calculated from a modified version of Ohm's law that takes into account both the electrical ($V_{\rm m}$) and chemical ($E_{\rm Na}$ or $E_{\rm K}$) driving forces on Na⁺ and K⁺:

$$I_{\rm K} = g_{\rm K}(V_{\rm m} - E_{\rm K})$$

and

$$I_{\text{Na}} = g_{\text{Na}}(V_{\text{m}} - E_{\text{Na}}).$$

Rearranging and solving for g gives two equations that can be used to compute the conductances of the active Na⁺ and K⁺ channel populations:

$$g_{K} = \frac{I_{K}}{(V_{m} - E_{K})}$$

and

$$g_{\text{Na}} = \frac{I_{\text{Na}}}{(V_{\text{m}} - E_{\text{Na}})}.$$

In these equations the independent variable $V_{\rm m}$ is set by the experimenter. The dependent variables $I_{\rm K}$ and $I_{\rm Na}$ can be calculated from the records of voltage-clamp experiments (see Figure 7–5). The parameters $E_{\rm K}$ and $E_{\rm Na}$ can be determined empirically by finding the values of $V_{\rm m}$ at which $I_{\rm K}$ and $I_{\rm Na}$ reverse their polarities, that is, their reversal potentials.

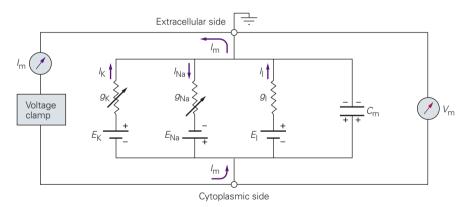

Figure 7–6 Equivalent circuit of a voltage-clamped neuron. The voltage-gated conductance pathways $(g_K \text{ and } g_{Na})$ are represented by the symbol for a variable conductance—a conductor (resistor) with an arrow through it. The conductance is variable because of its dependence on time and voltage. These conductances are

in series with batteries representing the chemical gradients for Na $^{\scriptscriptstyle +}$ and K $^{\scriptscriptstyle +}$. In addition there are parallel pathways for leakage current ($g_{\scriptscriptstyle \parallel}$ and $E_{\scriptscriptstyle \parallel}$) and capacitative current ($C_{\scriptscriptstyle m}$). Arrows indicate current flow during a depolarizing step that has activated $g_{\scriptscriptstyle K}$ and $g_{\scriptscriptstyle Na}$.

These variable, time-dependent effects of depolarization on g_{Na} are determined by the kinetics of two gating mechanisms in Na⁺ channels. Each Na⁺ channel has an *activation gate* that is closed while the membrane is at the resting potential and opened by depolarization. An *inactivation gate* is open at the resting potential and

closes after the channel opens in response to depolarization. The channel conducts Na⁺ only for the brief period during depolarization when *both* gates are open (Figure 7–9). Repolarization reverses the two processes, closing the activation gate and then opening the inactivation gate.

The Action Potential Can Be Reconstructed from the Properties of Sodium and Potassium Channels

Hodgkin and Huxley were able to fit their measurements of membrane conductance to a set of empirical equations that completely describe the Na⁺ and K⁺ conductances as a function of membrane potential and time. Using these equations and measured values for the passive properties of the axon, they computed the shape and conduction velocity of the action potential.

The calculated waveform of the action potential matched the waveform recorded in the unclamped axon almost perfectly. This close agreement indicates that the mathematical model developed by Hodgkin and Huxley accurately describes the properties of the channels that are essential for generating and propagating the action potential. More than a half-century later the Hodgkin-Huxley model stands as the most successful quantitative model in neural science if not in all of biology.

According to the Hodgkin-Huxley model an action potential involves the following sequence of

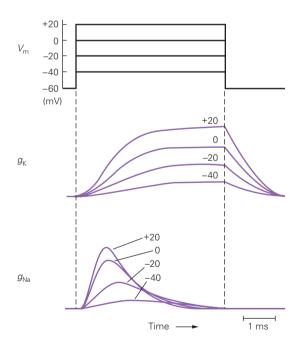

Figure 7–7 The responses of K⁺ and Na⁺ channels to prolonged depolarization. Increasing depolarizations elicit graded increases in K⁺ and Na⁺ conductance (g_{Na} and g_{k}), which reflect the proportional opening of thousands of voltage-gated K⁺ and Na⁺ channels. The Na⁺ channels open more rapidly than the K⁺ channels. During a maintained depolarization the Na⁺ channels close after opening because of the closure of an inactivation gate. The K⁺ channels remain open because they lack a fast inactivation process.

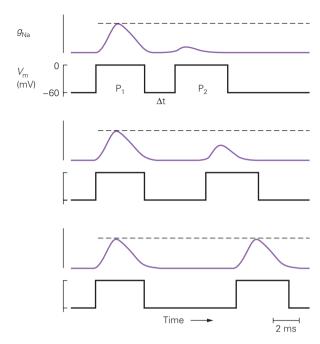

Figure 7–8 Sodium channels remain inactivated for a few milliseconds after a depolarizing current. If the interval (Δt) between two depolarizing pulses (P_1 and P_2) is brief, the second pulse produces a smaller increase in g_{Na} because many of the Na^+ channels remain inactivated after the first pulse. The longer the interval between pulses, the greater the increase in g_{Na} during the second pulse, because a greater fraction of channels will have recovered from inactivation during the period of repolarization and returned to the resting state when the second pulse begins. The time course of recovery from inactivation following repolarization contributes to determining the time course of the refractory period of an action potential.

events. Depolarization of the membrane causes Na^+ channels to open rapidly (an increase in g_{Na}), resulting in an inward Na^+ current. This current, by discharging the membrane capacitance, causes further depolarization, thereby opening more Na^+ channels, resulting in a further increase in inward current. This regenerative process drives the membrane potential toward E_{Na} , causing the rising phase of the action potential.²

²It may at first seem inconsistent to say that current flows *outward* across the membrane when a cell is depolarized experimentally (see Figure 6–2C), while attributing the depolarization during the upstroke of the action potential to an *inward* Na^+ current. However, in both cases the current across the capacitance of the membrane (C_m) is actually outward. It is simply as a matter of convention that we describe the direction of current injected through a microelectrode as the direction in which the injected current leaves the cell across the membrane capacitance, whereas we describe the direction of the ionic membrane current as the direction of charge movement through the channels.

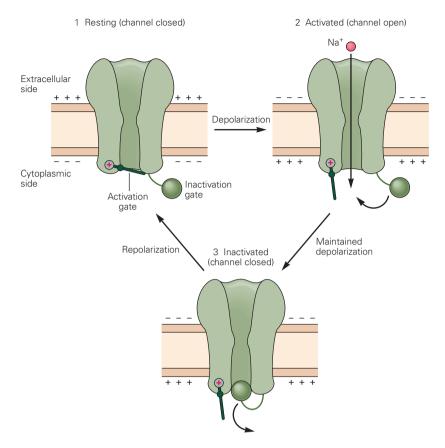

Figure 7–9 Voltage-gated Na⁺ channels have two gates that respond in opposite ways to depolarization. In the resting state the activation gate is closed and the inactivation gate is open (1). A depolarizing stimulus results in opening of the activation gate, allowing Na⁺ to flow through the channel, followed by closing of the inactivation gate (2). Once the inactivation gate has closed, the channel enters the inactivated state (3). On repolarization the inactivation gate opens and the activation gate closes as the channel returns to the resting state (1). The channel is only open during the brief period when both the activation and inactivation gates are open (2).

The depolarization limits the duration of the action potential in two ways: (1) It gradually inactivates the voltage-gated Na⁺ channels, thus reducing $g_{Na'}$, and (2) it opens, with some delay, the voltage-gated K⁺ channels, thereby increasing g_{K} . Consequently, the inward Na⁺ current is followed by an outward K⁺ current that tends to repolarize the membrane (Figure 7–10).

In most nerve cells the action potential is followed by a hyperpolarizing *after-potential*, a transient shift of the membrane potential to values more negative than the resting potential. This brief negative change in $V_{\rm m}$ occurs because the K⁺ channels that open during the repolarizing phase of the action potential remain open for some time after $V_{\rm m}$ has returned to its resting value. It takes a few milliseconds for all of the K⁺ channels to return to the closed state. During this time, when the permeability of the membrane to K⁺ is greater than during the resting state, $V_{\rm m}$ is slightly greater (more negative) than its normal resting value, resulting in a $V_{\rm m}$ closer to $E_{\rm K}$ (Figure 7–10).

The combined effect of this transient increase in K^+ conductance and the residual inactivation of the Na $^+$ channels (see Figure 7–10) underlies the *absolute*

refractory period, the brief period of time following an action potential when it is impossible to elicit another action potential. As some K⁺ channels begin to close and some Na⁺ channels recover from inactivation, the membrane enters the *relative refractory period*, during which it is possible to trigger an action potential, but only by applying stimuli that are stronger than those normally required to reach threshold. Together, these refractory periods typically last just 5–10 ms.

Two features of the action potential predicted by the Hodgkin-Huxley model are its threshold and allor-none behavior. A fraction of a millivolt can be the difference between a subthreshold stimulus and a stimulus that generates a full-sized action potential. This all-or-none phenomenon may seem surprising when one considers that $g_{\rm Na}$ increases in a strictly *graded* manner as depolarization increases (see Figure 7–7). Each increment of depolarization increases the number of voltage-gated Na $^+$ channels that open, thereby gradually increasing $I_{\rm Na}$. How then can there be a discrete threshold for generating an action potential?

Although a small subthreshold depolarization increases the inward $I_{Na'}$ it also increases two *outward*

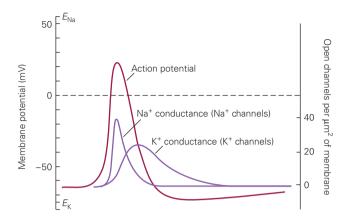

Figure 7–10 The sequential opening of voltage-gated Na⁺ and K⁺ channels generates the action potential. One of Hodgkin and Huxley's great achievements was to dissect the change in conductance during an action potential into separate components attributable to the opening of Na⁺ and K⁺ channels. The shape of the action potential and the underlying conductance changes can be calculated from the properties of the voltage-gated Na⁺ and K⁺ channels. (Adapted, with permission, from Hodgkin and Huxley 1952.)

currents, I_{K} and I_{I} , by increasing the electrochemical driving forces acting on K⁺ and Cl⁻. In addition, the depolarization augments g_K by gradually opening more voltage-gated K⁺ channels (Figure 7-7). As the outward I_{K} and I_{I} increase with depolarization they repolarize the membrane and resist the depolarizing action of the Na⁺ influx. However, because of the high voltage sensitivity and more rapid kinetics of activation of the Na⁺ channels, the depolarization eventually reaches a point where the increase in inward I_{Na} exceeds the increase in outward I_K and I_I . At this point there is a net inward ionic current. This produces a further depolarization, opening even more Na⁺ channels, so that the depolarization becomes regenerative, driving the membrane potential all the way to the peak of the action potential. The specific value of $V_{\rm m}$ at which the net ionic current $(I_{Na} + I_K + I_I)$ just changes from outward to inward, depositing a net positive charge on the inside of the membrane capacitance, is the threshold.

Variations in the Properties of Voltage-Gated Ion Channels Expand the Signaling Capabilities of Neurons

The basic mechanism of electrical excitability identified by Hodgkin and Huxley in the squid giant axon appears to be universal in all excitable cells: Voltage-gated channels conduct an inward Na⁺ current followed by an

outward K⁺ current. However, we now know that there are many types of voltage-gated Na⁺ and K⁺ channels encoded by families of related genes that are expressed in different nerve and muscle cells.

The biophysical properties of the various Na⁺ and K⁺ channels can differ both quantitatively and qualitatively from the channels characterized by Hodgkin and Huxley. Other gene families encode voltage-gated channels that select for Ca²⁺ ions or have mixed permeability to Na⁺ and K⁺. Moreover, the distribution of these channels can vary between different types of neurons, and can even vary as a function of locale within a single neuron. These differences in the pattern of ion channel expression have important consequences for membrane excitability, as we shall now explore.

The Nervous System Expresses a Rich Variety of Voltage-Gated Ion Channels

Voltage-gated Na⁺ and K⁺ channels similar to those described by Hodgkin and Huxley have been found in almost every type of neuron examined. In addition, most neurons contain voltage-gated Ca^{2+} channels that open in response to membrane depolarization. A strong electrochemical gradient drives Ca^{2+} into the cell, so these channels give rise to an inward I_{Ca} that helps depolarize the cell.

Some neurons and muscle cells have voltage-gated Cl $^-$ channels that contribute to membrane repolarization. Many neurons have cation channels that are slowly activated by hyperpolarization (instead of the usual depolarization). These hyperpolarization-activated cation (or HCN) channels are permeable to both K $^+$ and Na $^+$ and have a reversal potential around -40 to -30 mV. As a result, they give rise to an inward depolarizing current, referred to as $I_{\rm h}$, when the membrane repolarizes to negative resting potentials or becomes hyperpolarized during synaptic inhibition.

Each basic type of ion channel has many variants. For example, several types of voltage-activated K⁺ channels differ in their kinetics of activation, voltage-activation range, and sensitivity to various ligands. Four of these variants are particularly important in the nervous system. (1) The slowly activating K⁺ channel described by Hodgkin and Huxley is called the *delayed rectifier*. (2) The *calcium-activated K⁺ channel* is activated by an increase in intracellular Ca²⁺ when nearby voltage-gated Ca²⁺ channels open in response to depolarization. One subclass of calcium-activated K⁺ channels is voltage-dependent. However, in the absence of Ca²⁺ the channel requires very large, nonphysiological depolarization to open. The binding of Ca²⁺ to a site on the cytoplasmic surface of the channel shifts its voltage-gating

to allow the channel to open at more negative potentials. (3) The *A-type K*⁺ *channel* is activated rapidly by depolarization, almost as rapidly as the Na⁺ channel; like the Na⁺ channel, it also inactivates rapidly if the depolarization is prolonged. (4) The *M-type K*⁺ *channel* requires only small depolarizations from the resting potential to open; however, it activates very slowly, requiring tens of milliseconds to open. One distinctive feature of the M-type channel is that it is *closed* by a neurotransmitter, acetylcholine.

Similarly, at least five major types of voltage-gated Ca^{2+} channels and eight types of voltage-gated Na^+ channels are expressed in the nervous system. Each of these major subtypes is encoded by a different gene and has several structural and functional variants that are generated through alternative splicing or by combining the pore-forming α -subunit with different types of auxiliary subunits.

The squid axon can generate an action potential with just two types of voltage-gated channels. Why then are so many types of voltage-gated ion channels found in the nervous system? The answer is that neurons with a greater variety of voltage-gated channels have much more complex information-processing abilities than those with only two types of channels. Some ways in which various voltage-gated channels influence neuronal function are described below.

Gating of Voltage-Sensitive Ion Channels Can Be Influenced by Various Cytoplasmic Factors

In a typical neuron the opening and closing of certain voltage-gated ion channels can be modulated by various cytoplasmic factors, thus affording the neuron's excitability properties greater flexibility. Changes in the levels of such cytoplasmic factors may result from the activity of the neuron itself or from the influences of other neurons.

Calcium concentration is one important cytoplasmic factor that modulates ion channel activity. The ionic current through membrane channels during an action potential generally does not result in appreciable changes in the intracellular concentrations of most ion species. Calcium is a notable exception to this rule. The concentration of free Ca²⁺ in the cytoplasm of a resting cell is extremely low, about 10⁻⁷ M, several orders of magnitude below the external Ca²⁺ concentration, which is approximately 2 mM. For this reason the intracellular Ca²⁺ concentration may increase many fold above its resting value as a result of the influx of Ca²⁺ through voltage-gated Ca²⁺ channels. The transient increase in Ca²⁺ concentration near the inside of the membrane enhances the probability that calcium-activated,

voltage-sensitive K⁺ channels will open. Some Ca²⁺ channels are themselves sensitive to levels of intracellular Ca²⁺, becoming inactivated when incoming Ca²⁺ binds to their intracellular surface. Changes in the intracellular concentration of Ca²⁺ can also influence a variety of cellular metabolic processes, including neurotransmitter release and gene expression.

The activity of voltage-gated channels can also be regulated by the action of neurotransmitters through the recruitment of second-messenger pathways (see Chapter 11). These pathways can alter channel activity through a number of mechanisms, including direct phosphorylation of the intracellular domains of a channel or direct binding of cyclic nucleotides or membrane phosphoinositides to specialized binding domains in certain types of channels. As is true for the effects of Ca²⁺ binding, these pathways typically affect the kinetics or voltage sensitivity of channel gating rather than ion permeability of the open channel. The importance of cytoplasmic Ca²⁺ and other second messengers in the control of neuronal activity will become evident in many contexts throughout this book.

Excitability Properties Vary Between Regions of the Neuron

Different regions of a neuron have different types of ion channels that support the specialized functions of each region. The axon, for example, specializes in carrying signals faithfully over long distances; as such it functions as a relatively simple relay line. In contrast, the input, integrative, and output regions of a neuron (see Figure 2–9) typically perform more complex processing of the information they receive before passing it along.

Dendrites in many types of neurons have voltage-gated ion channels, including Ca²⁺, K⁺, HCN, and Na⁺ channels. When activated, these channels help shape the amplitude, time course, and propagation of the synaptic potentials to the cell body. In some neurons action potentials may be propagated from the trigger zone at the initial segment of the axon back into the dendrites, thereby influencing synaptic integration in the dendrites. In other neurons the density of voltage-gated channels in the dendrites is sufficient to support the generation of a local action potential, which may then be conducted through the cell soma to the axon initial segment.

The trigger zone at the axon initial segment has the lowest threshold for action potential generation in part because it has an exceptionally high density of voltage-gated Na⁺ channels. In addition, it typically has voltage-gated ion channels that are sensitive to relatively small deviations from the resting potential. These channels thus play a critical role in the transformation of graded synaptic or receptor potentials into a train of all-or-none action potentials. Examples include the M-type and certain A-type K⁺ channels, and a class of low voltage-activated Ca²⁺ channels (see below).

Conduction of the action potential down the axon is mediated primarily by voltage-gated Na⁺ and K⁺ channels that function much like those in the squid axon. In peripheral myelinated axons the mechanism of action potential repolarization at the nodes of Ranvier is particularly simple—the spike is terminated by fast inactivation of Na⁺ channels combined with a large outward K⁺ leakage current. Voltage-gated K⁺ channels play a relatively minor role in action potential repolarization in these peripheral axons. In contrast, some central myelinated axons have significant numbers of voltage-gated K⁺ channels at their nodes important for repolarization. Moreover, both central and peripheral myelinated axons have fairly high densities of K⁺ channels under the myelin sheath near the two ends of each internodal segment. The normal function of these K⁺ channels is to suppress any action potential that may be generated by axon membrane under the myelin sheath. In demyelinating diseases these channels become exposed and thus inhibit the ability of the bare axon to conduct action potentials (see Chapter 6).

Presynaptic nerve terminals at chemical synapses commonly have a high density of voltage-gated Ca²⁺ channels. Arrival of an action potential in the terminal opens these channels, causing an influx of Ca²⁺ that triggers transmitter release (Chapter 12).

Excitability Properties Vary Between Types of Neurons

Through the expression of a distinct complement of ion channels, the electrical properties of a neuron can be fine-tuned to match the dynamic demands of the information that it processes. Thus, although the function of a neuron is defined to a great extent by its synaptic inputs and outputs to other neurons, the excitability properties of the cell are also a critical factor in cell function.

Two aspects of excitability are important: (1) control of the shape of the action potential and (2) spike encoding, the process by which receptor potentials or synaptic potentials are converted into a temporal pattern of action potentials. Both of these features vary widely between different types of neurons. Of the voltage-gated channels, the K⁺ channels exhibit the greatest functional diversity. Differences in K⁺ channel expression are a key factor in determining the distinctive excitability properties of different classes of neurons.

How a neuron responds to synaptic input is determined by the proportions of different types of voltage-gated channels in the cell's input and integrative regions. For example, cells with different combinations of channels respond differently to a constant excitatory input. Some cells respond with only a single action potential, others with a train of action potentials at a constant rate of firing, and still others with either an accelerating or decelerating train of action potentials. The combined presence of certain voltage-gated Ca²⁺ channels and HCN channels generates pacemaker currents that allow some neurons to fire spontaneously in the absence of any external input (Figure 7–11D).

The firing rate of most neurons saturates as the strength of synaptic input increases, with a maximal rate that is not particularly high. However, certain classes of neurons have an unusually wide dynamic range and are able to fire at very high frequencies because of an unusually brief refractory period. This high firing rate is of particular importance in the auditory system, where neurons must respond to sound waves of very high frequencies. The short refractory period is caused, in part, by the expression in the auditory neurons of the voltage-gated K⁺ channel Kv3, whose activation gates close extremely rapidly following repolarization, resulting in a very short hyperpolarizing after-potential.

Some types of synaptic inputs to a neuron modulate the function of voltage-gated channels and thereby modulate the cell's response to other inputs. For example, in some neurons a steady hyperpolarizing synaptic input makes the cell less excitable by reducing the extent of inactivation of the A-type K⁺ channels that occurs at the normal resting potential of the cell. In other neurons such a steady hyperpolarization makes the cell *more* excitable because it reduces the inactivation of a particular class of voltage-gated Ca²⁺ channels. The firing properties of neurons can also be modulated by changing the function of certain voltage-gated ion channels, such as the M-type K⁺ channels, through synaptic activation of second messengers (Figure 7–11A–C).

Although the action potentials in a neuron under constant conditions are constant in shape, action potential duration and amplitude can vary depending on intrinsic neuronal activity and extrinsic synaptic inputs. Such changes can be particularly prominent in the input and output regions of the neuron. The longer the duration of the action potential, the longer the voltage-gated ion channels stay open and thus the greater the Ca²⁺ influx through voltage-gated Ca²⁺ channels. Changes in duration of the action potential therefore can play an important role in influencing events that are sensitive to cytoplasmic Ca²⁺ levels, such as ion channel

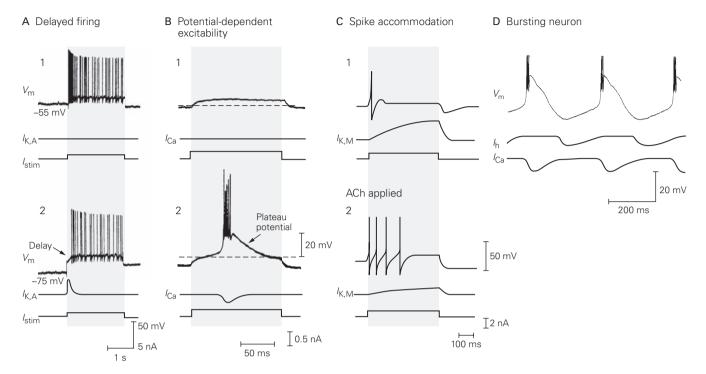

Figure 7–11 The response of a neuron to synaptic input is determined by its complement of voltage-gated ion channels. The waveform of the ionic current traces in the figure is drawn to reflect the activation and inactivation of the underlying conductances during the slow subthreshold changes in membrane potential. In reality, the currents will also show rapid changes during any triggered action potentials because of large, rapid changes in driving force.

A. Injection of a depolarizing current pulse $(I_{\rm stim})$ into a neuron in the nucleus tractus solitarius normally triggers an immediate train of action potentials (1). If the cell is first held at a hyperpolarized membrane potential, the spike train is delayed (2). The delay is caused by A-type K⁺ channels, which are activated by depolarizing synaptic input. The opening of these channels generates a transient outward K⁺ current, $I_{\rm K,A}$, that briefly drives $V_{\rm m}$ away from threshold. These channels typically are inactivated at the resting potential (–55 mV), but steady hyperpolarization removes the inactivation. (Reproduced, with permission, from Dekin and Getting 1987.)

B. A small depolarizing current pulse injected into a thalamic neuron at rest generates a subthreshold depolarization (1). If the membrane potential is held at a hyperpolarized level, the same current pulse triggers a burst of action potentials (2). The effectiveness of the current pulse is enhanced because the hyperpolarization causes a type of voltage-gated Ca^{2+} channel to recover from inactivation. Depolarizing inward current through the Ca^{2+} channels (I_{Ca}) generates a plateau potential of about 20 mV that triggers a burst of action potentials. The dashed line indicates the level of the normal resting potential. (Reproduced, with permission, from Llinás and Jahnsen 1982.)

The data in parts A and B demonstrate that steady hyperpolarization, such as might be produced by inhibitory synaptic input to a neuron, can profoundly affect the spike train pattern of a neuron. This effect varies greatly among cell types and depends on the presence or absence of particular types of voltage-gated Ca^{2^+} and K^+ channels.

C. The firing properties of sympathetic neurons in autonomic ganglia are regulated by a neurotransmitter. (1) A prolonged depolarizing current normally results in a single action potential. The depolarization turns on a slowly activated K⁺ current, the M current ($I_{K,M}$). The slow activation kinetics of the M-type channels allow the cell to fire one action potential before the efflux of K⁺ through the M-type channels becomes sufficient to shift the membrane to more negative voltages and prevent the cell from firing more action potentials (a process termed *accommodation*). (2) Synaptic release of the neurotransmitter acetylcholine (ACh) onto this neuron activates a second-messenger pathway that closes the M-type channels, allowing the cell to fire many action potentials in response to the same stimulus. (See also Figure 11–11.) (Reproduced, with permission, from Jones and Adams 1987.)

D. In the absence of synaptic input, thalamocortical relay neurons can fire spontaneously in brief bursts of action potentials. These bursts are produced by current through two types of voltage-gated ion channels. The gradual depolarization that leads to a burst is driven by inward current through HCN channels (I_p) , which have the unusual property of opening in response to hyperpolarizing voltage steps. The firing burst is triggered by an inward Ca2+ current through voltage-gated Ca2+ channels that are activated at relatively low levels of depolarization. This Ca²⁺ influx generates sufficient depolarization to reach threshold and drive a brief burst of Na⁺-dependent action potentials. The strong depolarization during the burst causes the HCN channels to close and inactivates the Ca²⁺ channels, allowing hyperpolarization to develop between bursts of firing. This hyperpolarization then opens the HCN channels, initiating the next cycle in the rhythm. (Reproduced, with permission, from McCormick and Huguenard 1992.)

gating, transmitter release, long-term changes in synaptic strength, and gene expression.

Extrinsic synaptic inputs can modulate action potential shape by activating second-messenger pathways that modulate the activity of certain voltagegated ion channels (see Chapter 11). The most common intrinsic modulation occurs during high-frequency firing, when there is a progressive buildup of inactivation of voltage-gated K⁺ channels that leads to a progressive increase in the duration of the later action potentials in a train. Some of the functional implications of these changes in action potential shape are considered in later chapters.

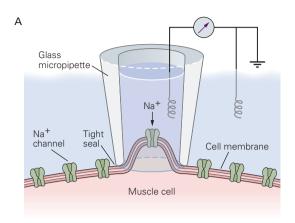

The Mechanisms of Voltage-Gating and Ion Permeation Have Been Inferred from Electrophysiological Measurements

The empirical equations derived by Hodgkin and Huxley are quite successful in describing how the flow of ions through the Na⁺ and K⁺ channels generates the action potential. However, these equations describe the process of excitation primarily in terms of changes in membrane conductance and current. They tell little about the mechanisms that activate or inactivate channels in response to changes in membrane potential or selectivity for specific ions.

Our understanding of the properties of ion channel molecules was greatly enhanced by patch-clamp studies of current through single channels (see Box 5–1). Patch-clamp experiments demonstrate that voltagegated channels generally have only two conductance states, open and closed. Recordings of single voltagegated Na⁺ channels show that, in response to a depolarization, a channel opens in an all-or-none fashion, conducting brief current pulses of constant amplitude but variable duration (Figure 7-12). During a maintained depolarization the open state of a channel is rapidly terminated by inactivation. Typical conductances of single voltage-gated Na⁺, K⁺, and Ca²⁺ channels range from 1 to 20 pS, depending on channel type. One class of calcium-activated K⁺ channel has an unusually large conductance of approximately 200 pS.

Voltage-Gated Sodium Channels Open and Close in Response to Redistribution of Charges Within the Channel

In their original study of the squid axon, Hodgkin and Huxley suggested that a voltage-gated channel has a net charge, the *gating charge*, somewhere within the membrane. They postulated that a change in membrane

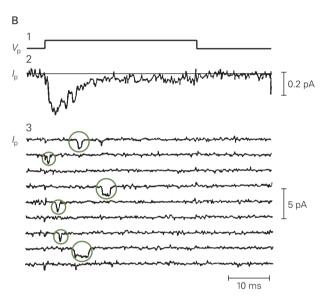

Figure 7–12 Individual voltage-gated channels open in an all-or-none fashion.

A. A small patch of membrane containing a single voltage-gated Na^+ channel is electrically isolated from the rest of the cell by the patch electrode. The Na^+ current that enters the cell through the channel is recorded by a current monitor connected to the patch electrode (see Box 5–1).

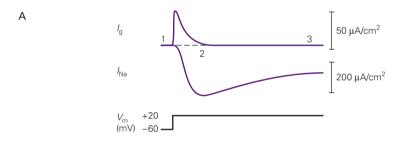

B. Recordings of single Na $^+$ channels in cultured muscle cells of rats. (1) Time course of a 10 mV depolarizing voltage step applied across the isolated patch of membrane (V_p = potential difference across the patch). (2) The sum of the inward current through the Na $^+$ channel in the patch during 300 trials (I_p = current through the patch). The trace was obtained by blocking the K $^+$ channels with tetraethylammonium and subtracting the leakage and capacitive currents electronically. (3) Nine individual trials from the set of 300, showing six openings of the channel (circles). These data demonstrate that the total Na $^+$ current recorded in a conventional voltage-clamp record (see Figure 7–3B) can be accounted for by the all-or-none opening and closing of a large number of Na $^+$ channels. (Reproduced, with permission, from Sigworth and Neher 1980.)

potential causes this charge to move across the electric field of the membrane, resulting in conformational changes that open or close the channel.

They further predicted that the movement of charge would be measurable. For example, they postulated that depolarization would move a positive gating charge from near the inner surface toward the outer surface of the membrane, owing to the interaction of the charge with the membrane electric field. This displacement would reduce the net separation of charge across the membrane and hence tend to hyperpolarize the membrane. To keep the membrane potential constant in a voltage-clamp experiment, a small extra component of outward capacitive current, called *gating current*, would have to be generated by the voltage clamp to counteract this rearrangement of charge within the membrane.

These predictions of Hodgkin and Huxley were later confirmed when the membrane current was examined by means of very sensitive techniques. The gating current was found to flow at the beginning and end of a depolarizing voltage-clamp step prior to the opening or closing of the Na⁺ channels (Figure 7–13).

Analysis of the gating current has provided additional insights into the mechanisms of voltage-gating. For example, it has revealed that activation and inactivation of Na⁺ channels are coupled processes. During a short depolarizing pulse the net outward movement of gating charge within the membrane at the beginning of the pulse is balanced by an equal and opposite movement of gating charge at the end of the pulse. However, if the pulse lasts long enough for Na⁺ channel inactivation to take place, the movement of gating charge back across the membrane at the end of the pulse is delayed. Some of the gating charge is thus temporarily immobilized; only as the Na⁺ channels recover from inactivation is that charge free to move back across the membrane. This charge immobilization indicates that some of the gating charges cannot move while the inactivation gate is closed.

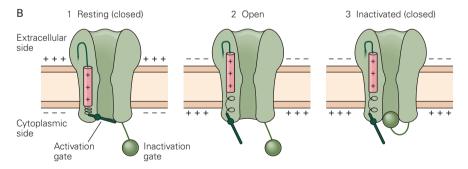

Figure 7–13 Changes in charge distribution within the Na⁺ channel are associated with opening and closing of the channel.

A. When the membrane is depolarized, the Na $^+$ current ($I_{\rm Na}$) is activated and then inactivated. The activation of the Na $^+$ current is preceded by a brief outward current ($I_{\rm g}$), reflecting the outward movement of positive charges within the Na $^+$ channels associated with the opening of their activation gates. To detect this small gating current it is necessary to block the flow of ionic current through the Na $^+$ and K $^+$ channels and mathematically subtract the

capacitive current due to charging of the lipid bilayer. (Adapted, with permission, from Armstrong and Gilly 1979).

B. The redistribution of gating charge and positions of the activation and inactivation gates when the channel is at rest, open, and inactivated. The **red cylinder** represents a positively charged region containing the gating charge that is thought to move through the membrane electric field in response to voltage changes. Depolarization from the resting state causes the gating charge to move outward, opening the activation gate. Inactivation closes the channel, immobilizing the gating charge.

To explain this immobilization phenomenon, Clay Armstrong and Francisco Bezanilla proposed that Na⁺ channel inactivation occurs when the open (activated) channel is blocked by a tethered plug (a ball and chain mechanism), thereby preventing the closure of the activation gate (Figure 7–13B). In support of this idea, exposing the inside of the axon to proteolytic enzymes selectively eliminates inactivation and its effect on gating charge. The Na⁺ channels remain open during a depolarization, and gating charge immobilization at the end of the pulse is eliminated—presumably because the enzymes clip off the inactivation "ball."

Voltage-Gated Sodium Channels Select for Sodium on the Basis of Size, Charge, and Energy of Hydration of the Ion

In Chapter 5 we saw how the structure of the K^+ channel pore could explain how such channels are able to select for K^+ over Na^+ ions. The narrow diameter of the K^+ channel selectivity filter (around 0.3 nm) requires that a K^+ or Na^+ ion must shed nearly all of its waters of hydration to enter the channel, an energetically unfavorable event.

The energetic cost of dehydration of a K^+ ion is well compensated by its close interaction with a cage of electronegative carbonyl oxygen atoms contributed by the peptide backbones of the four subunits of the K^+ channel selectivity filter. Because of its smaller radius, a Na^+ ion has a higher local electric field than does a K^+ ion and therefore interacts more strongly with its waters of hydration than does K^+ . On the other hand, the small diameter of the Na^+ ion precludes close interaction with the cage of carbonyl oxygen atoms in the selectivity filter; the resultant high energetic cost of dehydrating the Na^+ ion excludes it from entering the channel.

How then does the selectivity filter of the Na⁺ channel select for Na⁺ over K⁺ ions? Bertil Hille was able to deduce a model for the Na⁺ channel's selectivity mechanism from measurements of the channel's relative permeability to several types of organic and inorganic cations that differ in size and hydrogen-bonding characteristics. As we learned in Chapter 5, the channel behaves as if it contains a filter or recognition site that selects partly on the basis of size, thus acting as a molecular sieve (see Figure 5-1). Based on the size of the largest organic cation that could readily permeate the channel, Hille deduced that the selectivity filter had rectangular dimensions of 0.3×0.5 nm. This cross section is just large enough to accommodate one Na⁺ ion contacting one water molecule. Cations that are larger in diameter cannot pass through the pore. Cations smaller than this critical size pass through the pore, but only after losing most of the waters of hydration they normally carry in free solution.

The ease with which organic cations with good hydrogen-bonding characteristics pass through the channel suggests that part of the inner wall of the channel is made up of negatively polarized or charged amino acid residues that can substitute for the ion's waters of hydration. Lowering the pH of the fluid surrounding the cell reduces the conductance of the open channel, consistent with the titration of an important negatively charged carboxylic acid residue.

Based on these findings, Hille proposed that Na⁺ channels select for ions by the following mechanism. Negatively charged carboxylic acid groups of glutamate or aspartate residues at the outer mouth of the pore perform the first step in the selection process by attracting cations and repelling anions. The negative carboxylic acid groups, as well as other oxygen atoms that line the pore, can substitute for waters of hydration, but the degree of effectiveness of this substitution varies among ion species. For example, the negative charge of a carboxylic acid is able to form a stronger coulombic interaction with the smaller Na⁺ ion compared to the larger K⁺ ion. Because the Na⁺ channel is large enough to accommodate a cation in contact with several water molecules, the energetic cost of dehydration is not as great as it is in a K⁺ channel. As a result of these two features, the Na⁺ channel is able to select for Na⁺ over K⁺. A recent X-ray crystal structure of a bacterial voltage-gated Na+ channel has confirmed many of the key features of Hille's model.

Voltage-Gated Potassium, Sodium, and Calcium Channels Stem from a Common Ancestor and Have Similar Structures

Detailed molecular studies have revealed that all voltage-gated cation channels—those permeant to K⁺, Na⁺, or Ca²⁺—have a similar underlying architecture. In fact, there is now strong evidence from studies of bacteria, plants, invertebrates, and vertebrates that most voltage-sensitive cation channels stem from a common ancestral channel—perhaps a K⁺ channel—that can be traced to a single-cell organism living more than 1.4 billion years ago, before the evolution of separate plant and animal kingdoms. The amino acid sequences that are highly conserved through evolution help identify the domains within contemporary voltage-gated cation channels that are critical for function.

Voltage-gated cation channels are composed of pore-forming α -subunits that each contain a motif consisting of six transmembrane segments (S1–S6). A seventh hydrophobic region, the "P-region," connects the S5 and S6 segments. It forms a loop that dips into and out of the extracellular side of the membrane and forms

the channel's selectivity filter. All voltage-gated K⁺ channels consist of four pore-forming subunits, each of which contributes one P-region to the pore of the fully assembled channel. Voltage-gated Na⁺ and Ca²⁺ channels consist of one large pore-forming subunit

containing four internal repeats of this basic motif (Figure 7–14). The amino acid sequence of the S5-P-S6 region of voltage-gated K^+ channels is homologous to that of bacterial K^+ channels with two transmembrane segments.

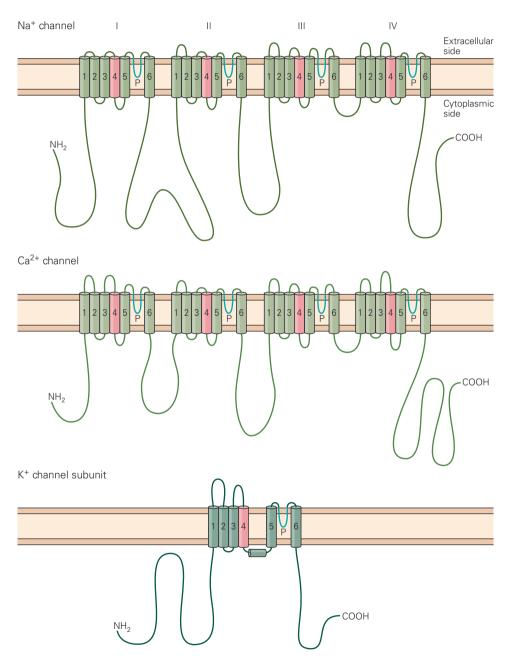

Figure 7–14 The voltage-gated cation channels have homologous α-subunit domains. The α-subunit of the Na⁺ and Ca²⁺ channels consists of a single polypeptide chain with four homologous repeats (I–IV) of a basic motif that contains six membrane-spanning α-helixes (S1–S6). The P-region between α-helixes 5 and 6 that dips into and out of the

membrane forms the selectivity filter. The S4 segment has a net positive charge. The α -subunit of the K⁺ channel, in contrast, has only one domain with six α -helixes and a P-region; four K⁺ channel α -subunits are assembled to form a complete channel (see Figure 5–12A). (Adapted, with permission, from Catterall 1988; Stevens 1991.)

The S4 segment is thought to play a particularly important role in voltage-gating. This transmembrane segment contains a distinctive pattern of amino acids in which every third position contains a positively charged arginine or lysine residue. The presence of so many positive charges within a single transmembrane segment is highly unusual. Because this pattern of positive charges is present in all voltage-gated channels but is absent in channels that are not voltage-gated, it is thought that this region might be the voltage sensor that part of the protein that transduces depolarization of the cell membrane into a conformational change that opens the channel. This idea is supported by experiments using site-directed mutagenesis, which show that neutralization of positive charges in S4 decreases the gating current and voltage sensitivity of channel activation.

X-Ray Crystallographic Analysis of Voltage-Gated Channel Structures Provides Insight into Voltage-Gating

How do the positive charges in S4 move through the membrane electric field during channel gating? How is S4 movement coupled to gating? What is the relationship of the voltage-sensing region to the pore-forming region of the channel? Insights into such questions have been provided by recent X-ray crystallographic structures of mammalian delayed rectifier voltage-gated K⁺ channels performed by Rod MacKinnon and his colleagues, as well as by a number of studies using mutagenesis and other biophysical approaches.

The X-ray crystal structures of the Kv1.2 channel and a Kv1.2-2.1 chimera show that a K⁺ channel subunit is composed of two domains. The S1–S4 segments form a voltage-sensing domain at the periphery of the channel while the S5-P-S6 region forms the pore domain at the central axis of the channel (Figure 7–15). The idea that the S1–S4 voltage sensor is a separate domain is consistent with the recent finding that certain bacterial proteins contain S1–S4 domains but lack a pore domain. One such protein is a voltage-sensitive phosphatase and a second protein forms a voltage-gated proton channel.

In the two-transmembrane segment bacterial K⁺ channels the four inner transmembrane helixes, which correspond to the S6 helixes in voltage-gated K⁺ channels, form a tight bundle crossing at their cytoplasmic ends to form the gate of the channel (see Figure 5–16). In the open state the inner ends of these helixes were seen to splay out to open the gate by bending at flexible glycine hinges. The structure of the Kv1.2-2.1 chimera indicates that the S6 helix is also bent at this conserved

glycine hinge so that the channel adopts an open conformation. It is not surprising that the Kv channel is in the open state as there is no voltage gradient across the channel in the crystals. This is similar to the situation in a membrane that has been depolarized to 0 mV, a voltage at which the channels are normally open.

One long-standing question in studies of voltagegating is how the charges on the voltage-sensor overcome the unfavorable energy change associated with their positioning within the nonpolar membrane where they must sense the electric field. The crystal structure provides some answers to this question. Mutagenesis studies indicate that four positively charged arginine residues in the external half of the S4 segment are likely to carry most of the gating charge. In the open state the four positive charges face outward toward the extracellular side of the membrane, where they may undergo energetically favorable interactions with water or the negatively charged head groups of the phospholipid bilayer. Positive charges on other S4 residues that lie more deeply within the lipid bilayer are stabilized by interactions with negatively charged acidic residues on the S1-S3 transmembrane helixes.

At present a crystal structure for the closed state of the channel is lacking. However, MacKinnon and colleagues have proposed a plausible model for voltagegating based on the structures of the open voltagegated K⁺ channel and the closed two-transmembrane segment bacterial K⁺ channel (Figure 7–16). According to this model, a negative voltage inside the cell exerts a force on the positively charged S4 helix that causes it to move inward by about 1.0 to 1.5 nm. As a result, the four positively charged S4 residues that in the depolarized state face the external environment and sense the extracellular potential now face the intracellular side of the membrane and sense the intracellular potential. In this manner movement of each S4 segment will translocate 3-4 electronic charges across the membrane electric field as the channel transitions between the closed and open states, for a total of 12–16 charges moved per tetrameric channel. This number is very similar to the total charge movement determined from gating current measurements.

How are S4 movements coupled to the gate of the channel? According to the model, the inward movement of the S4 segment when the membrane voltage becomes negative exerts a downward force on an α-helix that couples the S4 and S5 transmembrane segments. This S4-S5 coupling helix lies roughly parallel to the membrane at its cytoplasmic surface. In the open state the S4-S5 helix rests on the inner end of the S6 helix gate. As a result, downward movement of the helix applies force to S6, closing the gate. Thus

voltage-gating is thought to rely on the electromechanical coupling between the voltage-sensing domain and the pore domain of the channel. Although this electromechanical coupling model provides a very satisfying picture for how changes in membrane voltage lead to channel gating, a definitive answer to this key problem will require resolution of the structure of the closed state of a voltage-gated channel.

The Diversity of Voltage-Gated Channel Types Is Generated by Several Genetic Mechanisms

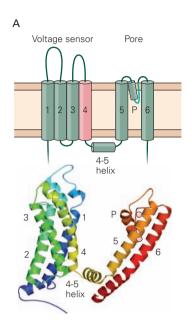

The conservative mechanism by which evolution proceeds—creating new structural or functional entities by duplicating, modifying, shuffling, and recombining existing gene-coding sequences—is illustrated by the modular design of the members of the extended gene family that encodes the voltage-gated Na⁺, K⁺, and Ca²⁺ channels. This family also includes genes that encode calcium-activated K⁺ channels, the hyperpolarization-activated HCN channels, and a voltage-independent cyclic nucleotide-gated cation channel important for phototransduction and olfaction.

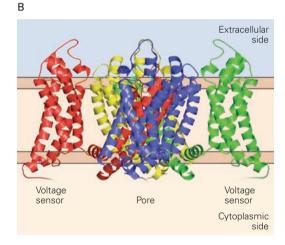

The functional differences between these channels are caused by differences in amino acid sequence in their core transmembrane domains as well as by the addition of regulatory domains to the C-terminal cytoplasmic end of the proteins. Some of these cytoplasmic domains bind either Ca²⁺ or cyclic nucleotides, enabling these agents to regulate channel gating (Figure 7–17).

A. Top: In addition to its six transmembrane α -helixes (S1–S6), a voltage-gated K⁺ channel subunit contains a short α -helix (the P helix) that is part of the P-region selectivity filter, as well as an α -helix on the cytoplasmic side of the membrane that connects transmembrane helixes S4 and S5 (4-5). Bottom: An X-ray structural model of a single subunit shows the positions of the six membrane-spanning helixes, the P helix, and the 4-5 linker helix. Note how the S1–S4 voltage-sensing region and S5-P-S6 pore-forming region are localized in separate domains. Two potassium ions bound in the pore are shown in pink.

- **B.** Side view of the tetrameric voltage-gated K⁺ channel. Each individual subunit is highlighted in a different color. The red subunit is in the same orientation as the subunit shown above in panel part A. The approximate position of the lipid bilayer is indicated (tan colors).
- C. A view looking down on the tetrameric channel from outside the cell. The four voltage-sensors (S1–S4) are located on the periphery and the S5-P-S6 pore-forming region of the channel is in the center. A potassium ion is shown in the center of the pore (pink). (Adapted, with permission, from Long et al. 2007.)

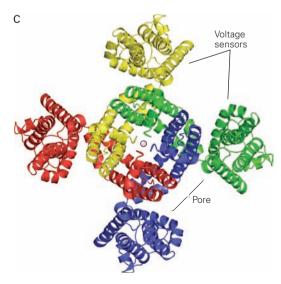

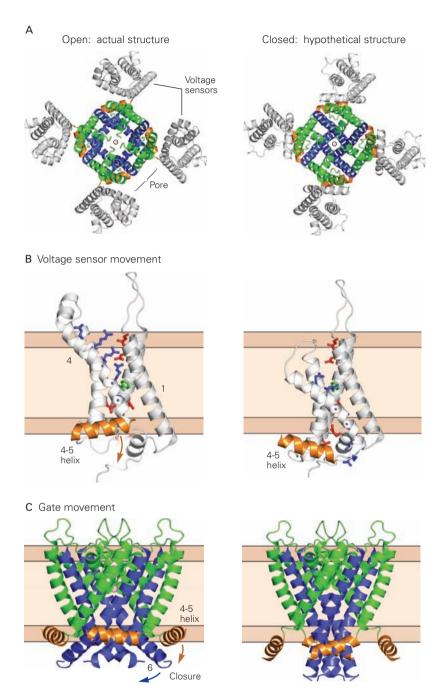

Figure 7–16 Model for voltage-gating based on X-ray crystal structures of two K⁺ channels. The drawings on the left show the actual structure of an open voltage-gated K⁺ channel (from the crystal structure shown in Figure 7–15). The drawings on the right show the hypothetical structure of a closed voltage-gated K⁺ channel, based in part on the structure of the pore region of the two-transmembrane segment bacterial K⁺ channel KcsA in the closed state. (Adapted, with permission, by Yu-hang Chen from Long et al. 2007.)

- **A.** A view looking down on the open and closed channel from outside the cell. Note how the central pore is constricted in the closed state. This constriction prevents K⁺ flow through the channel.
- B. A view of the S1-S4 voltage-sensing domain from the side, parallel to the plane of the membrane. Positively charged residues in S4 are shown as blue sticks. In the open state, when the membrane is depolarized, four positive charges on the S4 helix are located in the external half of the membrane, facing the external solution. The positive charges in the interior of the membrane are stabilized by interactions with negatively charged residues in S1 and S2 (red sticks). In the closed state, when the membrane potential is negative, the S4 region moves inward so that its positive charges now lie in the inner half of the membrane. The inward movement of S4 causes the cytoplasmic S4-S5 coupling helix to move downward.
- C. The putative conformational change in the channel pore upon voltage-gating. A side view of the tetrameric S5-P-S6 pore region of the channel shows the S4-S5 coupling helix. Membrane repolarization causes the downward movement of the S4-S5 helix, applying force to the S6 inner helix of the pore. This causes the S6 helix to bend at its glycine hinge, thereby closing the gate of the channel.

As we saw in Chapter 5, the four subunits that comprise the inward-rectifying K⁺ channels are truncated versions of the fundamental structural motif; they consist of only the P region and its two flanking membrane-spanning regions. Evolution has provided many of these channels with an extrinsic mechanism of voltage sensitivity through the addition of an internal cationic binding site. When the cell is depolarized,

cytoplasmic Mg²⁺ or positively charged polyamines (small organic molecules that are normal constituents of the cytoplasm) are electrostatically driven to this binding site from the cytoplasm, plugging the channel.

Inactivation of voltage-gated ion channels is also mediated by different molecular modules. For example, the rapid inactivation of both the A-type K⁺ channel and the voltage-gated Na⁺ channel is mediated by

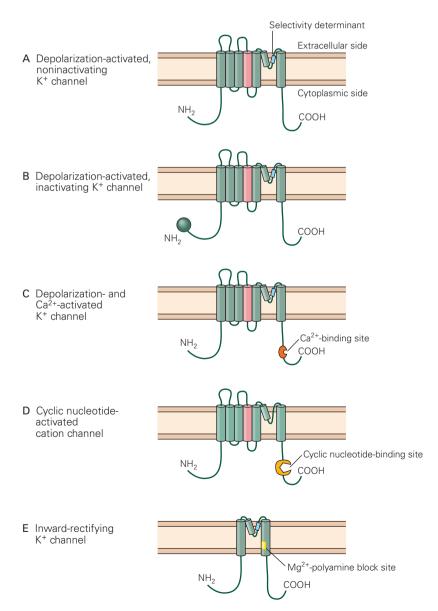

a tethered plug that binds to the inner mouth of the channel when the activation gate opens. In the A-type K^+ channel the plug is formed by the cytoplasmic N-terminus of the channel protein, whereas in voltage-gated Na^+ channels it is formed by the cytoplasmic loop connecting domains III and IV of the α -subunit.

The wide range of firing properties of different neurons and the ability of a single neuron to adapt its firing to a range of synaptic inputs depends on the large diversity of ion channels expressed throughout the nervous system. Even a single ion species, such as K^+ , can cross the membrane through several distinct types of channels, each with its own characteristic

kinetics, voltage dependence, and sensitivity to different modulators. For voltage-gated channels five different mechanisms are responsible for this diversity. (1) More than one gene may encode related α -subunits within one class of channel. For example, eight different genes that encode voltage-gated Na⁺ channel α -subunits are expressed in the mammalian nervous system. (2) The four α -subunits that form a K⁺ channel may be encoded by different genes. After translation the α -subunits are in some cases mixed and matched in various combinations, thus forming different subclasses of heteromultimeric channels. (3) A single gene product may be alternatively spliced, resulting in

Figure 7–17 The extended gene family of voltage-gated channels produces variants of a common molecular design.

- A. The basic transmembrane topology of an α -subunit of a voltage-gated K^+ channel.
- **B.** Many K⁺ channels that are first activated and then inactivated by prolonged depolarization have a ball-and-chain segment at their N-terminal end that inactivates the channel by plugging its inner mouth.
- C. Some K⁺ channels that require both depolarization and an increase in intracellular Ca²⁺ to activate have a Ca²⁺-binding sequence attached to the C-terminal end of the channel.
- D. Cation channels gated by cyclic nucleotides have a cyclic nucleotide-binding domain attached to the C-terminal end. One class of such channels includes the voltage-independent, cyclic nucleotide-gated channels important in the transduction of olfactory and visual sensory signals. Another subclass consists of the hyperpolarization-activated (HCN) channels important for pacemaker activity (see Figure 7–11D). The P loops in these channels lack key amino acid residues required for K⁺ selectivity. As a result, these channels do not show a high degree of discrimination between Na⁺ and K⁺.
- E. Inward-rectifying K⁺ channels, which are gated by blocking particles available in the cytoplasm, are formed from a truncated version of the basic building block, with only two membrane-spanning regions and a P-region.

variations in the messenger RNA (mRNA) molecules that encode the $\alpha\text{-subunit.}$ (4) The RNA that encodes an $\alpha\text{-subunit}$ may be edited by chemical modification of a single nucleotide, thereby changing the composition of a single amino acid in the channel subunit. (5) One type of $\alpha\text{-subunit}$ may be combined with different accessory subunits to form functionally different channel types.

These accessory subunits (often termed β -, γ -, or δ -subunits) may be either cytoplasmic or membrane-spanning and can produce a wide range of effects on channel function. For example, some β -subunits enhance the efficiency with which the channel is trafficked to the membrane. Other subunits regulate channel gating, either enhancing or inhibiting the coupling of depolarization to channel opening. In some K⁺ channels the α -subunit lacks a tethered inactivation plug; the association of such α -subunits with β -subunits that contain their own N-terminal tethered plugs can endow the channel with the ability to rapidly inactivate. In contrast to the α -subunits, there is no known homology among the β -, γ -, and δ -subunits from the three major subfamilies of voltage-gated channels.

These various sources of channel diversity also vary widely between different areas of the nervous system, between different types of neurons, and within different subcellular compartments of a given neuron. A corollary of this regional differentiation is that mutations or epigenetic mechanisms that alter voltage-gated channel function can have very selective effects on neuronal or muscular function. The result is a large array of neurological diseases called channelopathies (see Chapter 14).

An Overall View

An action potential is produced when ions move across the cell membrane through voltage-gated channels and thereby change the charge separation across the membrane. An influx of Na⁺, and in some cases Ca²⁺, depolarizes the membrane and initiates the action potential. An efflux of K⁺ then repolarizes the membrane by restoring the initial charge separation. A particularly important subset of voltage-gated channels opens primarily when the membrane potential nears the threshold for an action potential; these channels have a profound effect on the spike-train encoding properties of a neuron.

We know much about how channels function from studies that use variations of the voltage-clamp technique—these studies let us eavesdrop on a channel at work. And we know a good deal from biochemical, molecular biological, and X-ray crystallographic studies about the channel's structure—about the primary amino acid sequence of the proteins that form them and how these proteins adopt their detailed secondary, tertiary, and quaternary structures in the membrane.

Now these two approaches are being combined in a concerted effort to understand the relationship between structure and function in these channels: how the detailed three-dimensional structure of the molecule and the chemical and physical properties of its individual residues gives rise to the remarkable gating and ion permeation properties of the voltage-gated channels. Thus, we may soon be able to understand the molecular mechanism for the remarkable ability of voltage-gated channels to generate the action potential. These insights into channel function have two important practical implications. They will allow us to understand better the molecular bases of certain genetic diseases that involve mutations in ion channel genes, and they will enable us to design safer and more effective drugs to treat a variety of diseases that involve disturbances in electrical signaling (such as epilepsy, multiple sclerosis, myotonia, and ataxia).

Synaptic Transmission

In Part II, we examined how electrical signals are initiated and propagated within an individual neuron. We now turn to synaptic transmission, the process by which one nerve cell communicates with another. An average neuron forms and receives 1,000 to 10,000 synaptic connections, and the human brain contains at least 10¹¹ neurons. Thus 10¹⁴ to 10¹⁵ synaptic connections are formed in the brain. There are 1,000-fold more synapses in one brain than the 100 billion stars in our galaxy! Fortunately, only a few basic mechanisms underlie synaptic transmission at these many connections.

With some exceptions, the synapse consists of three components: (1) the terminals of the presynaptic axon, (2) a target on the postsynaptic cell, and (3) a zone of apposition. Based on the structure of the apposition, synapses are categorized into two major groups: electrical and chemical. At electrical synapses, the presynaptic terminal and the postsynaptic cell are in very close apposition at regions termed gap junctions. The current generated by an action potential in the presynaptic neuron directly enters the postsynaptic cell through specialized bridging channels called gap junction channels, which physically connect the cytoplasm of the presynaptic and postsynaptic cells. At chemical synapses, a cleft separates the two cells, and the cells do not communicate through bridging channels. Rather, an action potential in the presynaptic cell leads to the release of a chemical transmitter from the nerve terminal. The transmitter diffuses across the synaptic cleft and binds to receptor molecules on the postsynaptic membrane, which regulates the opening and closing of ion channels in the postsynaptic cell. This leads to changes in the membrane potential of the postsynaptic neuron that can either excite or inhibit the firing of an action potential.

Receptors for transmitters can be classified into two major groups depending on how they control ion channels in the postsynaptic cell. One type, the ionotropic receptor, is an ion channel that opens when the transmitter binds. The second type, the metabotropic receptor, acts indirectly on ion channels by activating a biochemical second-messenger cascade within the postsynaptic cell. Both types of receptors can result in excitation or inhibition. The sign of the signal depends not on the identity of the transmitter but on the properties of the receptor with which the transmitter interacts. A single transmitter can produce several distinct effects by activating different types of receptors. Thus, receptor diversity permits a relatively small number of transmitters to produce a wide variety of synaptic actions. Most transmitters are low-molecular-weight molecules, but certain peptides also can act as messengers at synapses. The methods of electrophysiology, biochemistry, and molecular biology have been used to characterize the

receptors in postsynaptic cells that respond to these various chemical messengers. These methods have also clarified how second-messenger pathways transduce signals within cells.

In this part of the book, we consider synaptic transmission in its most elementary forms. We first compare and contrast the two major classes of synapses, chemical and electrical (see Chapter 8). We then focus on a model chemical synapse in the peripheral nervous system, the neuromuscular junction between a presynaptic motor neuron and postsynaptic skeletal muscle fiber (see Chapter 9). Next we examine the principles of chemical synapses between neurons in the central nervous system, focusing on the postsynaptic cell and its integration of thousands of synaptic signals from multiple presynaptic inputs, which involve both ionotropic receptor-mediated signals (see Chapter 10) as well as metabotropic receptor-mediated signals (see Chapter 11). We then turn to the presynaptic terminal and consider the mechanisms by which neurons release transmitter from their presynaptic terminals, how transmitter release can be regulated by neural activity (see Chapter 12), and the chemical nature of the neurotransmitters (see Chapter 13). Because the molecular architecture of chemical synapses is complex, many diseases can affect chemical synaptic transmission (see Chapter 14). One disorder that we consider in detail in this section is myasthenia gravis, a disease that disrupts transmission at synapses between spinal motor neurons and skeletal muscle. Analysis of abnormalities in synaptic transmission associated with human disease is important clinically. At the same time clinical studies have provided critical insight into mechanisms that underlie normal synaptic function.

Overview of Synaptic Transmission

Synapses Are Either Electrical or Chemical

Electrical Synapses Provide Instantaneous Signal Transmission

Cells at an Electrical Synapse Are Connected by Gap-Junction Channels

Electrical Transmission Allows the Rapid and Synchronous Firing of Interconnected Cells

Gap Junctions Have a Role in Glial Function and Disease

Chemical Synapses Can Amplify Signals

Neurotransmitters Bind to Postsynaptic Receptors

Postsynaptic Receptors Gate Ion Channels Either Directly or Indirectly

THAT GIVES NERVE CELLS THEIR SPECIAL ABILITY to communicate with one another rapidly and with such great precision? We have already seen how signals are propagated within a neuron, from its dendrites and cell body to its axonal terminals. With this chapter we begin to consider the signaling between neurons through the process of synaptic transmission.

The specialized site at which one neuron communicates with another is called a *synapse*, and synaptic transmission is fundamental to the neural functions we consider later in the book, such as perception, voluntary movement, and learning.

The average neuron forms several thousand synaptic connections and receives a similar number. The Purkinje cell of the cerebellum receives up to 100,000 synaptic inputs. Although many of these connections are highly specialized, all neurons make use of one of

the two basic forms of synaptic transmission: electrical or chemical. Moreover, the strength of both forms of synaptic transmission can be enhanced or diminished by cellular activity. This *plasticity* of synapses is crucial to memory and other higher brain functions.

Electrical synapses are employed primarily to send rapid and stereotyped depolarizing signals. In contrast, chemical synapses are capable of more variable signaling and thus can produce more complex behaviors. They can mediate either excitatory or inhibitory actions in postsynaptic cells and produce electrical changes in the postsynaptic cell that last from milliseconds to many minutes. Chemical synapses also serve to amplify neuronal signals, so even a small presynaptic nerve terminal can alter the response of large postsynaptic cells. Not surprisingly, most synapses in the brain are chemical. Because chemical synaptic transmission is so central to understanding brain and behavior, it is examined in detail in the next four chapters.

Synapses Are Either Electrical or Chemical

The term *synapse* was introduced at the beginning of the twentieth century by Charles Sherrington to describe the specialized zone of contact at which one neuron communicates with another. This site had first been described histologically at the level of light microscopy by Ramón y Cajal in the late 19th century.

All synapses were initially thought to operate by means of electrical transmission. In the 1920s, however, Otto Loewi discovered that the chemical compound acetylcholine (ACh) conveys signals from the vagus nerve to the heart. Loewi's discovery provoked considerable debate in the 1930s over whether chemical signaling existed at other synapses, including synapses between motor nerve and skeletal muscle as well as synapses in the brain.

Two schools of thought emerged, one physiological and the other pharmacological. Each championed a single mechanism for all synaptic transmission. Led by John Eccles (Sherrington's student), the physiologists argued that synaptic transmission is electrical, that the action potential in the presynaptic neuron generates a current that flows passively into the postsynaptic cell. The pharmacologists, led by Henry Dale, argued that transmission is chemical, that the action potential in the presynaptic neuron leads to the release of a chemical substance that in turn initiates current in the postsynaptic cell. When physiological and ultrastructural techniques improved in the 1950s and 1960s, it became clear that both forms of transmission exist. Although a chemical transmitter is used at most synapses, some operate purely by electrical means.

Once the fine structure of synapses was made visible with the electron microscope, chemical and electrical synapses were found to have different structures. At chemical synapses the presynaptic and postsynaptic neurons are completely separated by a small space, called the synaptic cleft; there is no continuity between the cytoplasm of one cell and the next. In contrast, at electrical synapses the pre- and postsynaptic cells communicate through special channels, the *gap-junction channels*, that directly connect the cytoplasm of the two cells.

The main functional properties of the two types of synapses are summarized in Table 8–1. The most important difference can be observed by injecting a positive current into the presynaptic cell to elicit a depolarization.

At both types of synapses outward current across the presynaptic cell membrane deposits positive charge on the inside of the presynaptic cell membrane, thereby depolarizing the cell (see Chapter 6). At electrical synapses some of the current will enter the postsynaptic cell through the gap-junction channels, depositing a positive charge on the inside of the membrane and depolarizing it. The current leaves the postsynaptic cell across the membrane capacitance and through resting channels (Figure 8–1A). If the depolarization exceeds threshold, voltage-gated ion channels in the postsynaptic cell open and generate an action potential. By contrast, at chemical synapses there is no direct low-resistance pathway between the pre- and postsynaptic cells. Instead, the action potential in the presynaptic neuron initiates the release of a chemical transmitter, which diffuses across the synaptic cleft to interact with receptors on the membrane of the postsynaptic cell (Figure 8–1B).

Electrical Synapses Provide Instantaneous Signal Transmission

During excitatory synaptic transmission at an electrical synapse, voltage-gated ion channels in the presynaptic cell generate the current that depolarizes the postsynaptic cell. Thus these channels not only depolarize the presynaptic cell above the threshold for an action potential but also generate sufficient ionic current to produce a change in potential in the postsynaptic cell.

To generate such a large current, the presynaptic terminal must be big enough for its membrane to contain many ion channels. At the same time, the postsynaptic

Table 8–1 Distinguishing Prope	rties of Electrical and Chemical Synapses
--------------------------------	---

Type of synapse	Distance between pre- and postsynaptic cell membranes	Cytoplasmic continuity between pre- and postsynaptic cells	Ultrastructural components	Agent of transmission	Synaptic delay	Direction of transmission
Electrical	4 nm	Yes	Gap-junction channels	Ion current	Virtually absent	Usually bidirectional
Chemical	20–40 nm	No	Presynaptic vesicles and active zones; postsynaptic receptors	Chemical transmitter	Significant: at least 0.3 ms, usually 1–5 ms or longer	Unidirectional

A Current pathways at electrical synapses

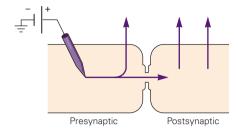

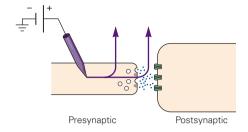

Figure 8–1 Functional properties of electrical and chemical synapses.

A. At an electrical synapse some current injected into the presynaptic cell escapes through resting (nongated) ion channels in the cell membrane. However, some current also enters the postsynaptic cell through gap-junction channels that connect the cytoplasm of the pre- and postsynaptic cells and that provide a low-resistance (high-conductance) pathway for electrical current.

cell must be relatively small. This is because a small cell has a higher input resistance ($R_{\rm in}$) than a large cell and, according to Ohm's law ($\Delta V = I \times R_{\rm in}$), undergoes a greater voltage change (ΔV) in response to a given presynaptic current (I).

B Current pathways at chemical synapses

B. At chemical synapses all current injected into the presynaptic cell escapes into the extracellular fluid. However, the resulting depolarization of the presynaptic cell membrane can produce an action potential that causes the release of neurotransmitter molecules that bind receptors on the postsynaptic cell. This binding opens ion channels that initiate a change in membrane potential in the postsynaptic cell.

Electrical synaptic transmission was first described by Edwin Furshpan and David Potter in the giant motor synapse of the crayfish, where the presynaptic fiber is much larger than the postsynaptic fiber (Figure 8–2A). An action potential generated in the presynaptic fiber

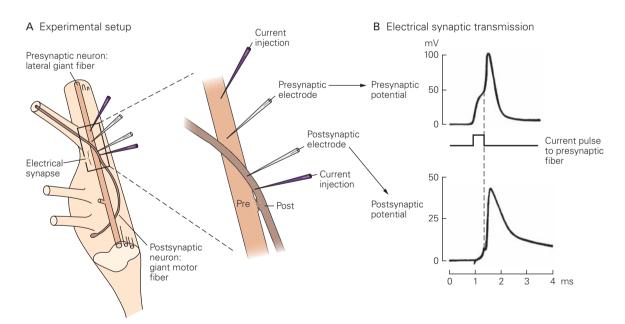

Figure 8–2 Electrical synaptic transmission was first demonstrated at the giant motor synapse in the crayfish. (Adapted, with permission, from Furshpan and Potter 1957 and 1959.)

A. The lateral giant fiber running down the nerve cord is the presynaptic neuron. The giant motor fiber, which projects from the cell body in the ganglion to the periphery, is the postsynaptic neuron. Electrodes for passing current and for recording voltage are placed within the pre- and postsynaptic cells.

B. Transmission at an electrical synapse is virtually instantaneous—the postsynaptic response follows presynaptic stimulation in a fraction of a millisecond. The dashed line shows how the responses of the two cells correspond in time. At chemical synapses there is a delay (the synaptic delay) between the pre- and postsynaptic potentials (see Figure 8–8).

produces a depolarizing postsynaptic potential that often exceeds the threshold to fire an action potential. At electrical synapses, the synaptic delay—the time between the presynaptic spike and the postsynaptic potential—is remarkably short (Figure 8–2B).

Such a short latency is not possible with chemical transmission, which requires several biochemical steps: release of a transmitter from the presynaptic neuron, diffusion of transmitter molecules to the postsynaptic cell, binding of transmitter to a specific receptor, and subsequent gating of ion channels (all described later in this chapter). Only current passing directly from one cell to another can produce the near-instantaneous transmission observed at the giant motor synapse.

Another feature of electrical transmission is that the change in potential of the postsynaptic cell is directly related to the size and shape of the change in potential of the presynaptic cell. Even when a weak subthreshold depolarizing current is injected into the presynaptic neuron, some current enters the postsynaptic cell and depolarizes it (Figure 8–3). In contrast, at a chemical synapse the current in the presynaptic cell must reach the threshold for an action potential before it can release transmitter and elicit a response in the postsynaptic cell.

Most electrical synapses can transmit both depolarizing and hyperpolarizing currents. A presynaptic action potential with a large hyperpolarizing afterpotential produces a biphasic (depolarizing-hyperpolarizing) change in potential in the postsynaptic cell. Signal transmission at electrical synapses

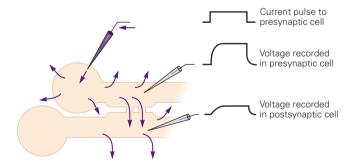

Figure 8–3 Electrical transmission is graded and occurs even when the current in the presynaptic cell is below the threshold for an action potential. This can be demonstrated by depolarizing the presynaptic cell with a small current pulse through one electrode while the membrane potential is recorded with a second electrode. A subthreshold depolarizing stimulus causes a passive depolarization in the presynaptic and postsynaptic cells. (Depolarizing or outward current is indicated by an upward deflection.)

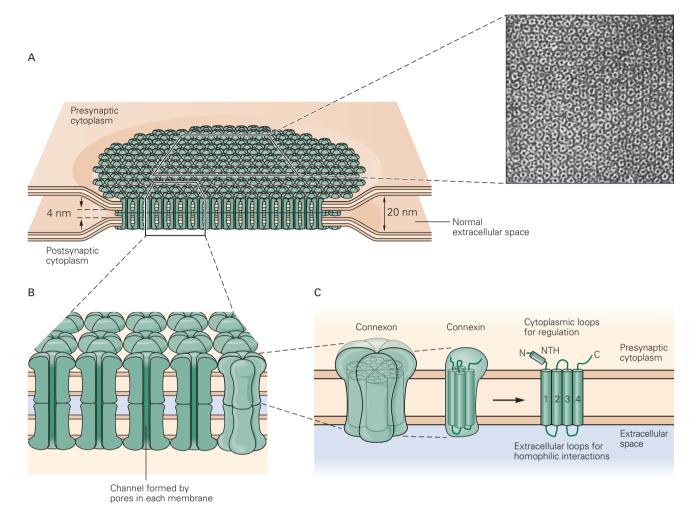

is similar to the passive propagation of subthreshold electrical signals along axons (see Chapter 6) and therefore is also referred to as *electrotonic transmission*. At some specialized gap junctions the channels have voltage-dependent gates that permit them to conduct depolarizing current in only one direction, from the presynaptic cell to the postsynaptic cell. These junctions are called *rectifying synapses*. (The crayfish giant motor synapse is an example.)

Cells at an Electrical Synapse Are Connected by Gap-Junction Channels

The specialized region of contact between two neurons at an electrical synapse is termed the *gap junction*. Here the separation between the two neurons (4 nm) is much less than the normal nonsynaptic space between neurons (20 nm). This narrow gap is bridged by the gap-junction channels, specialized protein structures that conduct ionic current from the presynaptic to the postsynaptic cell.

A gap-junction channel consists of a pair of hemichannels, or connexons, one in the presynaptic and the other in the postsynaptic cell membrane. These hemichannels thus form a continuous bridge that provides a direct communication path between the two cells (Figure 8–4). The pore of the channel has a large diameter of approximately 1.5 nm, which permits inorganic ions and small organic molecules and experimental markers such as fluorescent dyes to pass between the two cells.

Each hemichannel or connexon is composed of six identical subunits, called connexins. Connexins in different tissues are encoded by a large gene family containing more than 20 members. All connexin subunits have an intracellular N- and C-terminus with four interposed α -helixes that span the cell membrane (Figure 8-4C). Many gap-junction channels in different cell types are formed by the products of different connexin genes and thus respond differently to modulatory factors that control their opening and closing. For example, although most gap-junction channels close in response to lowered cytoplasmic pH or elevated cytoplasmic Ca²⁺, the sensitivity of different channel isoforms to these factors varies widely. This pH and Ca²⁺dependent closing of gap-junction channels plays an important role in the decoupling of damaged cells from healthy cells, because damaged cells contain elevated Ca²⁺ levels and a high concentration of protons. Finally, neurotransmitters released from nearby chemical synapses can modulate the opening of gap-junction channels through intracellular metabolic reactions (see Chapter 11).

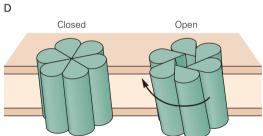

Figure 8–4 A three-dimensional model of the gap-junction channel, based on X-ray and electron diffraction studies.

A. The electrical synapse, or gap junction, is composed of numerous specialized channels that span the membranes of two neurons. These gap-junction channels allow current to pass directly from one cell to the other. The array of channels shown in the electron micrograph was isolated from the membrane of a rat liver. The tissue has been negatively stained, a technique that darkens the area around the channels and in the pores. Each channel appears hexagonal in outline. Magnification ×307,800. (Reproduced, with permission, from N. Gilula.)

- **B.** A gap-junction channel is actually a pair of hemichannels, one in each apposite cell that connects the cytoplasm of the two cells. (Adapted, with permission, from Makowski et al. 1977.)
- C. Each hemichannel, or connexon, is made up of six identical subunits called connexins. Each connexin is approximately

7.5 nm long and spans the cell membrane. A single connexin has intracellular N- and C-termini, including a short intracellular N-terminal α -helix (NTH), and four membrane-spanning α -helixes (1–4). There are regions of similarity in the amino acid sequences of gap-junction proteins from many different kinds of tissue. These include the transmembrane helixes and the extracellular regions, which are involved in the homophilic matching of apposite hemichannels.

D. The connexins are arranged in such a way that a pore is formed in the center of the structure. The resulting connexon, with a pore diameter of approximately 1.5 to 2 nm, has a characteristic hexagonal outline, as shown in part A. In some gap-junction channels the pore is opened when the subunits rotate approximately 0.9 nm at the cytoplasmic base in a clockwise direction. (Reproduced, with permission, from Unwin and Zampighi 1980.)

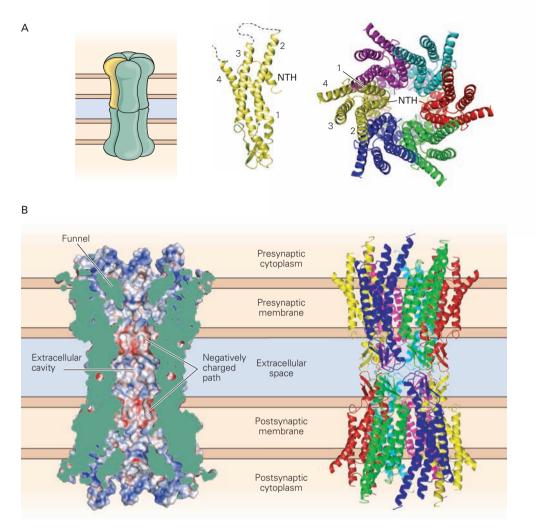

Figure 8–5 High-resolution three-dimensional structure of a gap-junction channel. All structures were determined by X-ray crystallography of gap-junction channels formed by the human connexon 26 subunit. (Reproduced, with permission, from Maeda et al., 2009.)

A. Left: Diagram of an intact gap-junction channel showing the pair of apposed hemichannels in the pre- and postsynaptic cells. Middle: High-resolution structure of a single connexin subunit showing the presence of four transmembrane α -helixes (1–4) and a short N-terminal helix (NTH). The orientation of the subunit corresponds to that of the yellow subunit in the diagram to the left. Right: Bottom-up view looking into a hemichannel from the cytoplasm. Each of the six subunits has a different color. The helixes of the yellow subunit are numbered. The orientation

corresponds to that of the yellow hemichannel in the diagram at left, following a 90° rotation toward the viewer.

B. Two side views of the gap-junction channel in the plane of the membrane show the two apposed hemichannels. The orientation is the same as in the panel of part A. Left: Cross-section through the channel shows the internal surface of the channel pore. Blue indicates positively charged surfaces, and red indicates negatively charged surfaces. The green mass inside the pore at the cytoplasmic entrance (funnel) is thought to represent the channel gate formed by the N-terminal helix. Right: A side view of the channel shows each of the six connexin subunits in the same color scheme as in part A. The entire gap-junction channel is approximately 9 nm wide by 15 nm tall.

The three-dimensional structure of a gap-junction channel formed by the human connexin 26 subunit has recently been determined by X-ray crystallography. This structure shows in detail how the membrane-spanning α -helixes assemble to form the central pore of the channel and how the extracellular loops connecting the transmembrane helixes interdigitate to connect the

two hemichannels (Figure 8–5). The pore is lined with polar residues that facilitate the movement of ions. An N-terminal α -helix may serve as the voltage gate of the connexin 26 channel, plugging the cytoplasmic mouth of the pore in the closed state. A separate gate at the extracellular side of the channel, formed by the extracellular loop connecting the first two membrane helixes,

has been inferred from functional studies. This loop gate is thought to close isolated hemichannels that are not docked to a hemichannel partner in the apposing cell.

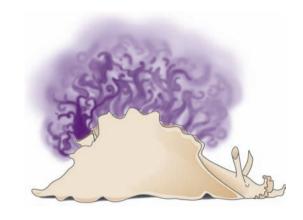

Electrical Transmission Allows the Rapid and Synchronous Firing of Interconnected Cells

How are electrical synapses useful? As we have seen, transmission across electrical synapses is extremely rapid because it results from the direct passage of current between cells. Speed is important for escape responses. For example, the tail-flip response of goldfish is mediated by a giant neuron in the brain stem (known as the Mauthner cell), which receives sensory input at electrical synapses. These electrical synapses rapidly depolarize the Mauthner cell, which in turn activates the motor neurons of the tail, allowing rapid escape from danger.

Electrical transmission is also useful for orchestrating the actions of large groups of neurons. Because current crosses the membranes of all electrically coupled cells at the same time, several small cells can act coordinately as one large cell. Moreover, because of

the electrical coupling between the cells, the effective resistance of the coupled network of neurons is smaller than the resistance of an individual cell. Thus, from Ohm's law, the synaptic current required to fire electrically coupled cells is larger than that necessary to fire an individual cell. That is, electrically coupled cells have a higher firing threshold. Once this high threshold is surpassed, however, electrically coupled cells fire synchronously because voltage-activated Na⁺ currents generated in one cell are very rapidly conducted to other cells.

Thus a behavior controlled by a group of electrically coupled cells has an important adaptive advantage: It is triggered explosively. For example, when seriously perturbed, the marine snail *Aplysia* releases massive clouds of purple ink that provide a protective screen. This stereotypic behavior is mediated by three electrically coupled motor cells that innervate the ink gland. Once the action potential threshold is exceeded in these cells, they fire synchronously (Figure 8–6). In certain fish, rapid eye movements (called saccades) are also mediated by electrically coupled motor neurons

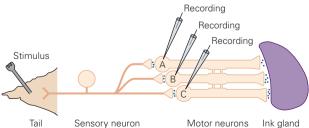

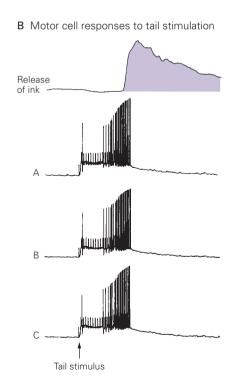

Figure 8–6 Electrically coupled motor neurons firing together can produce synchronous behaviors. (Adapted, with permission, from Carew and Kandel 1976.)

A. In the marine snail *Aplysia* sensory neurons from the tail ganglion form synapses with three motor neurons that

innervate the ink gland. The motor neurons are interconnected by electrical synapses.

B. A train of stimuli applied to the tail produces a synchronized discharge in all three motor neurons that results in the release of ink.

firing together. Gap junctions are also important in the mammalian brain, where the synchronous firing of electrically coupled inhibitory interneurons generates synchronous, high-frequency oscillations.

In addition to providing speed or synchrony in neuronal signaling, electrical synapses also can transmit metabolic signals between cells. Because gap-junction channels are relatively large and nonselective, they conduct a variety of inorganic cations and anions, including the second messenger Ca²⁺, and even allow moderate-sized organic compounds (less than 1,000 Da molecular weight)—such as the second messengers inositol 1,4,5-trisphosphate (IP₃), cyclic adenosine monophosphate (cAMP), and even small peptides—to pass from one cell to the next.

Gap Junctions Have a Role in Glial Function and Disease

Gap junctions are formed between glial cells as well as between neurons. In glia the gap junctions mediate both intercellular and intracellular communication. In the brain individual astrocytes are connected to each other through gap junctions, which mediate communication between them, forming a glial cell network. Electrical stimulation of neuronal pathways in brain slices can release neurotransmitters that trigger a rise in intracellular Ca^{2+} in certain astrocytes. This produces a wave of Ca^{2+} that propagates at a rate of approximately 1 $\mu\text{m/s}$, traveling from astrocyte to astrocyte by diffusion through gap-junction channels. Although the precise function of the waves is unknown, their existence suggests that glia may play an active role in signaling in the brain.

Gap-junction channels also enhance communication within certain glial cells, the Schwann cells that produce the myelin sheath of axons in the peripheral nervous system. Successive layers of myelin formed by a single Schwann cell are connected by gap junctions. These gap junctions may help to hold the layers of myelin together and promote the passage of small metabolites and ions across the many layers of myelin. The importance of the Schwann cell gap-junction channels is underscored by certain genetic diseases. For example, the X chromosome-linked form of Charcot-Marie-Tooth disease, a demyelinating disorder, is caused by single mutations in a connexin gene (connexin 32) expressed in the Schwann cell that blocks gap-junction channel function. Inherited mutations that prevent the function of a connexin expressed in the cochlea (connexin 26) underlie up to half of all instances of congenital deafness. This connexin normally forms gap-junction channels that are important for fluid secretion in the inner ear.

Chemical Synapses Can Amplify Signals

In contrast to electrical synapses, at chemical synapses there is no structural continuity between pre- and postsynaptic neurons. In fact, the separation between the two cells at a chemical synapse, the synaptic cleft, is usually wider (20–40 nm) than the nonsynaptic intercellular space (20 nm). Chemical synaptic transmission depends on the diffusion of a neurotransmitter across the synaptic cleft. A neurotransmitter is a chemical substance that binds receptors in the postsynaptic membrane of the target cell. At most chemical synapses transmitter is released from specialized swellings of the axon, the presynaptic terminals, which typically contain 100 to 200 synaptic vesicles, each of which is filled with several thousand molecules of the neurotransmitter (Figure 8–7).

The synaptic vesicles are clustered at specialized regions of the presynaptic membrane called *active zones*, which are the sites of neurotransmitter release. During a presynaptic action potential, voltage-gated Ca²⁺ channels at the active zone open, allowing Ca²⁺ to enter the presynaptic terminal. The rise in intracellular Ca²⁺ concentration triggers a biochemical reaction that causes the vesicles to fuse with the presynaptic membrane and release neurotransmitter into the synaptic cleft, a process termed *exocytosis*. The transmitter

Figure 8–7 The fine structure of a presynaptic terminal. This electron micrograph shows a synapse in the cerebellum. The large dark structures are mitochondria. The many small round bodies are vesicles that contain neurotransmitter. The fuzzy dark thickenings along the presynaptic membrane (arrows) are the active zones, specialized areas that are thought to be docking and release sites for synaptic vesicles. The synaptic cleft is the space just outside the presynaptic terminal separating the pre- and postsynaptic cell membranes. (Reproduced, with permission, from J. E. Heuser and T. S. Reese.)

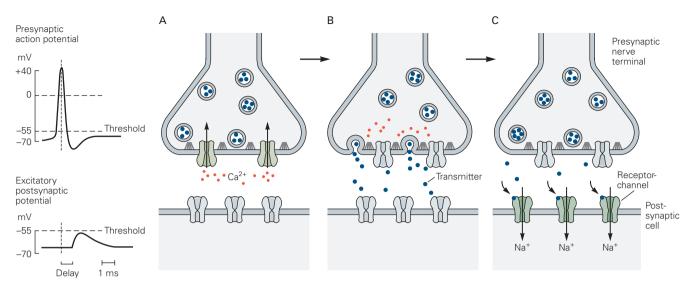

Figure 8–8 Synaptic transmission at chemical synapses involves several steps. The complex process of chemical synaptic transmission accounts for the delay between an action potential in the presynaptic cell and the synaptic potential in the postsynaptic cell compared with the virtually instantaneous transmission of signals at electrical synapses (see Figure 8–2B).

A. An action potential arriving at the terminal of a presynaptic axon causes voltage-gated Ca²⁺ channels at the active zone to open. The **gray filaments** represent the docking and release sites of the active zone.

B. The Ca²⁺ channel opening produces a high concentration of intracellular Ca²⁺ near the active zone, causing vesicles containing neurotransmitter to fuse with the presynaptic cell membrane and release their contents into the synaptic cleft (a process termed *exocytosis*).

C. The released neurotransmitter molecules then diffuse across the synaptic cleft and bind specific receptors on the postsynaptic membrane. These receptors cause ion channels to open (or close), thereby changing the membrane conductance and membrane potential of the postsynaptic cell.

molecules then diffuse across the synaptic cleft and bind to their receptors on the postsynaptic cell membrane. This in turn activates the receptors, leading to the opening or closing of ion channels. The resulting flux of ions alters the membrane conductance and potential of the postsynaptic cell (Figure 8–8).

These several steps account for the synaptic delay at chemical synapses, a delay that can be as short as 0.3 ms but often lasts several milliseconds. Although chemical transmission lacks the speed of electrical synapses, it has the important property of *amplification*. Just one synaptic vesicle releases several thousand molecules of transmitter that together can open thousands of ion channels in the target cell. In this way a small presynaptic nerve terminal, which generates only a weak electrical current, can depolarize a large postsynaptic cell.

Neurotransmitters Bind to Postsynaptic Receptors

Chemical synaptic transmission can be divided into two steps: a transmitting step, in which the presynaptic cell releases a chemical messenger, and a receptive step, in which the transmitter binds to and activates the receptor molecules in the postsynaptic cell. The transmitting process resembles endocrine hormone release. Indeed, chemical synaptic transmission can be seen as a modified form of hormone secretion. Both endocrine glands and presynaptic terminals release a chemical agent with a signaling function, and both are examples of regulated secretion (Chapter 4). Similarly, both endocrine glands and neurons are usually some distance from their target cells. There is one important difference, however, between endocrine and synaptic signaling. Whereas the hormone released by a gland travels through the blood stream until it interacts with all cells that contain an appropriate receptor, a neuron usually communicates only with the cells with which it forms synapses. Because the presynaptic action potential triggers the release of a chemical transmitter onto a target cell across a distance of only 20 nm, the chemical signal travels only a small distance to its target. Therefore, neuronal signaling has two special features: It is fast and precisely directed.

To accomplish this directed or focused release, most neurons have specialized secretory machinery, the active zones, which are directly apposed to the transmitter receptors in the postsynaptic cell. In neurons without active zones, the distinction between neuronal and hormonal transmission becomes blurred.

For example, the neurons in the autonomic nervous system that innervate smooth muscle reside at some distance from their postsynaptic cells and do not have specialized release sites in their terminals. Synaptic transmission between these cells is slower and relies on a more widespread diffusion of transmitter. Furthermore, the same transmitter substance can be released differently from different cells. From one cell a substance can be released as a conventional transmitter acting directly on neighboring cells. From other cells it can be released in a less focused way as a modulator, producing a more diffuse action; and from still other cells it can be released into the blood stream as a neurohormone.

Although a variety of chemicals serve as neuro-transmitters, including both small molecules and peptides (see Chapter 13), the action of a transmitter depends on the properties of the postsynaptic receptors that recognize and bind the transmitter, not the chemical properties of the transmitter. For example, ACh can excite some postsynaptic cells and inhibit others, and at still other cells it can produce both excitation and inhibition. It is the receptor that determines the action of ACh, including whether a cholinergic synapse is excitatory or inhibitory.

Within a group of closely related animals, a transmitter substance binds conserved families of receptors and can be often associated with specific physiological functions. In vertebrates ACh acts on excitatory ACh receptors at all neuromuscular junctions to trigger contraction and it acts on inhibitory ACh receptors to slow the heart.

The notion of a receptor was introduced in the late 19th century by the German bacteriologist Paul Ehrlich to explain the selective action of toxins and other pharmacological agents and the great specificity of immunological reactions. In 1900 Ehrlich wrote: "Chemical substances are only able to exercise an action on the tissue elements with which they are able to establish an intimate chemical relationship . . . [This relationship] must be specific. The [chemical] groups must be adapted to one another . . . as lock and key."

In 1906 the English pharmacologist John Langley postulated that the sensitivity of skeletal muscle to curare and nicotine was caused by a "receptive molecule." A theory of receptor function was later developed by Langley's students (in particular, A.V. Hill and Henry Dale), a development that was based on concurrent studies of enzyme kinetics and cooperative interactions between small molecules and proteins. As we shall see in the next chapter, Langley's "receptive molecule" has been isolated and characterized as the ACh receptor of the neuromuscular junction.

All receptors for chemical transmitters have two biochemical features in common:

- They are membrane-spanning proteins. The region exposed to the external environment of the cell recognizes and binds the transmitter from the presynaptic cell.
- 2. They carry out an effector function within the target cell. The receptors typically influence the opening or closing of ion channels.

Postsynaptic Receptors Gate Ion Channels Either Directly or Indirectly

Neurotransmitters control the opening of ion channels in the postsynaptic cell either directly or indirectly. These two classes of transmitter actions are mediated by receptor proteins derived from different gene families.

Receptors that gate ion channels directly, such as the ACh receptor at the neuromuscular junction, are composed of four or five subunits that form a single macromolecule. Such receptors contain both an extracellular domain that forms the binding site for the transmitter and a membrane-spanning domain that forms an ion-conducting pore (Figure 8–9A). This kind of receptor is often referred to as *ionotropic*. Upon binding neurotransmitter, the receptor undergoes a conformational change that opens the channel. The actions of ionotropic receptors, also called *receptor-channels* or *ligand-gated channels*, are discussed in detail in Chapters 9 and 10.

Receptors that gate ion channels indirectly, like the several types of receptors for norepinephrine or dopamine in neurons of the cerebral cortex, are normally composed of one or at most two subunits that are distinct from the ion channels they regulate. These receptors, which commonly have seven membrane-spanning α-helixes, act by altering intracellular metabolic reactions and are often referred to as metabotropic receptors. Activation of these receptors often stimulates the production of second messengers, small freely diffusible intracellular metabolites such as cAMP or diacylglycerol. Many of these second messengers activate protein kinases, enzymes that phosphorylate different substrate proteins. In many instances the protein kinases directly phosphorylate ion channels, leading to their opening or closing (Figure 8-9B). The actions of metabotropic receptors are examined in detail in Chapter 11.

Ionotropic and metabotropic receptors have different functions. The ionotropic receptors produce relatively fast synaptic actions lasting only milliseconds. These are commonly found at synapses in neural circuits that mediate rapid behaviors, such as the stretch

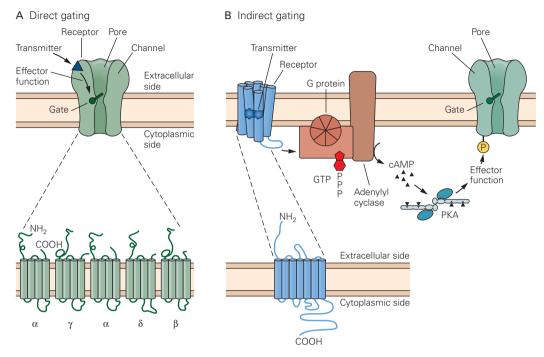

Figure 8–9 Neurotransmitters open postsynaptic ion channels either directly or indirectly.

A. A receptor that directly opens ion channels is an integral part of the macromolecule that also forms the channel. Many such ligand-gated channels are composed of five subunits, each of which is thought to contain four membrane-spanning $\alpha\text{-helical}$ regions.

B. A receptor that indirectly opens an ion channel is a distinct macromolecule separate from the channel it regulates. In one large family of such receptors, the receptors are composed of a

single subunit with seven membrane-spanning α -helical regions that bind the ligand within the plane of the membrane. These receptors activate a guanosine triphosphate (GTP)–binding protein (G protein), which in turn activates a second-messenger cascade that modulates channel activity. In the cascade illustrated here the G protein stimulates adenylyl cyclase, which converts adenosine triphosphate (ATP) to cAMP. The cAMP activates the cAMP-dependent protein kinase (PKA), which phosphorylates the channel (P), leading to a change in function.

receptor reflex. The metabotropic receptors produce slower synaptic actions lasting seconds to minutes. These slower actions can modulate behavior by altering the excitability of neurons and the strength of the synaptic connections of the neural circuitry mediating behavior. Such modulatory synaptic actions often act as crucial reinforcing pathways in the process of learning.

ommunication between neurons in the brain relies mainly on chemical synapses. Much of our present understanding of the function of these synapses is based on studies of synaptic transmission at the nerve-muscle synapse, the junction between a motor neuron and a skeletal muscle fiber. This is the site where synaptic transmission was first studied and remains best understood. Moreover, the nerve-muscle synapse is the site of a number of inherited and acquired neurological diseases. Therefore, before we examine the complexities of synapses in the central

nervous system, we will examine the basic features of chemical synaptic transmission at the nerve-muscle synapse.

The nerve-muscle synapse is an ideal site for studying chemical signaling because it is relatively simple and accessible to experimentation. The muscle cell is large enough to accommodate the two or more microelectrodes needed to make electrical measurements. Also the muscle cell normally receives signals from just one presynaptic axon, in contrast to the convergent connections on central nerve cells. Most importantly, chemical signaling at the nerve-muscle synapse involves a relatively simple mechanism: Release of neurotransmitter from the presynaptic nerve directly opens a single type of ion channel in the postsynaptic membrane.

The Neuromuscular Junction Is a Well-Studied Example of Directly Gated Synaptic Transmission

The motor neuron innervates the muscle at a specialized region of the muscle membrane called the *endplate*, where the motor axon loses its myelin sheath and splits into several fine branches. The ends of the fine branches form multiple expansions or varicosities, called *synaptic boutons*, from which the motor neuron releases its transmitter. Each bouton is positioned over a specialized region of the muscle membrane containing deep depressions, or *junctional folds*, which contain the transmitter receptors (Figure 9–1). The transmitter released by the motor axon terminal is acetylcholine

Figure 9–1 The neuromuscular junction is an ideal site for studying chemical synaptic signaling. At the muscle the motor axon ramifies into several fine branches approximately 2 µm thick. Each branch forms multiple swellings called synaptic boutons, which are covered by a thin layer of Schwann cells. The boutons lie over a specialized region of the muscle fiber membrane, the end-plate, and are separated from the muscle membrane by a 100-nm synaptic cleft. Each bouton contains mitochondria and synaptic vesicles clustered around active zones, where the neurotransmitter acetylcholine (ACh) is released. Immediately under each bouton in the end-plate are several junctional folds, the crests of which contain a high density of ACh receptors.

The muscle fiber and nerve terminal are covered by a layer of connective tissue, the basal lamina, consisting of collagen and glycoproteins. Unlike the cell membrane, the basal lamina is freely permeable to ions and small organic compounds, including the transmitter. Both the presynaptic terminal and the muscle fiber secrete proteins into the basal lamina, including the enzyme acetylcholinesterase, which inactivates the ACh released from the presynaptic terminal by breaking it down into acetate and choline. The basal lamina also organizes the synapse by aligning the presynaptic boutons with the postsynaptic junctional folds. (Adapted, with permission, from McMahan and Kuffler 1971.)

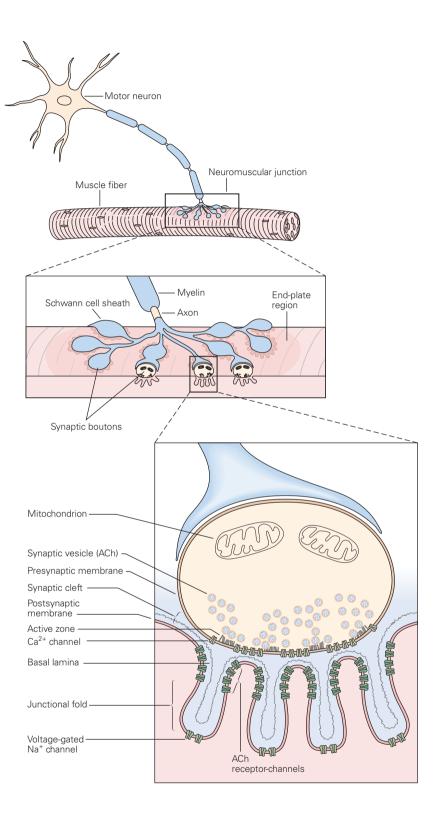

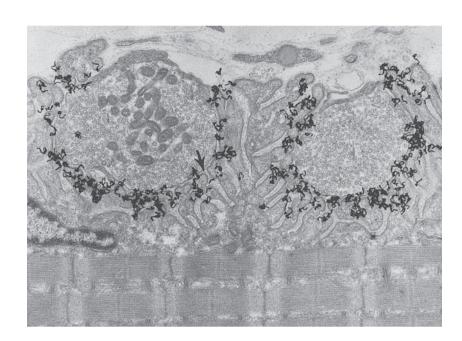

Figure 9–2 Acetylcholine receptors in the vertebrate neuromuscular junction are concentrated at the top one-third of the junctional folds. This receptor-rich region is characterized by an increased density of the postjunctional membrane (arrow). The autoradiograph shown here was made by first incubating the membrane with radiolabeled α -bungarotoxin, which binds to the ACh receptor (black grains). Radioactive decay results in the emittance of a particle that causes overlaid silver grains to become fixed along its trajectory (black grains). Magnification ×18,000. (Reproduced, with permission, from Salpeter 1987.)

(ACh) and the receptor on the muscle membrane is the nicotinic type of ACh receptor.¹

The presynaptic and postsynaptic membranes are separated by a synaptic cleft approximately 100 nm wide. Within the cleft is a basal lamina (or basement membrane) composed of collagen and other extracellular matrix proteins. The enzyme acetylcholinesterase, which rapidly hydrolyzes ACh, is anchored to the collagen fibrils of the basal laminae. In the muscle cell, in the region below the crest of the junctional fold and extending into the fold, the membrane is rich in voltage-gated Na⁺channels (Figure 9–1).

Each synaptic bouton contains all the machinery required to release neurotransmitter. This includes the synaptic vesicles, which contain the transmitter ACh, and the active zones, regions of the membrane specialized for release of transmitter, where the synaptic vesicles are clustered (Figure 9–1). In addition, each active zone contains voltage-gated Ca²⁺ channels that permit Ca²⁺ to enter the terminal with each action potential (see Figure 9–1). This influx of Ca²⁺ triggers the fusion of the synaptic vesicles with the plasma membrane at the active zones, releasing the contents of the synaptic vesicle into the synaptic cleft by the process of exocytosis

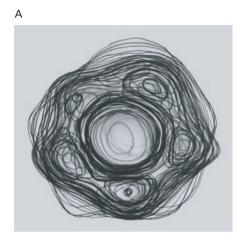

(see Chapter 12). Every active zone in the presynaptic membrane is positioned opposite a junctional fold in the postsynaptic cell. At the crest of each fold the receptors for ACh are clustered in a lattice, with a density of approximately 10,000 receptors per μ m² (Figure 9–2). The nicotinic ACh receptor is a ligand-gated channel: It is an integral membrane protein that both binds ACh and forms an ion channel (Figure 9–3).

The Motor Neuron Excites the Muscle by Opening Ligand-Gated Ion Channels at the End-Plate

The release of transmitter from the motor nerve terminal opens ACh receptor-channels in the muscle membrane at the end-plate, and this action rapidly depolarizes the membrane. The resulting excitatory postsynaptic potential (EPSP), also called the *end-plate potential* at the nerve-muscle synapse, is very large; stimulation of a single motor cell produces a synaptic potential of approximately 70 mV.

This change in membrane potential usually is large enough to rapidly activate the voltage-gated Na⁺ channels in the junctional folds, converting the end-plate potential into an action potential, which then propagates along the muscle fiber. In contrast, in the central nervous system most presynaptic neurons produce postsynaptic potentials less than 1 mV in amplitude. As a result, input from many presynaptic neurons is needed to generate an action potential in most neurons.

¹There are two basic types of receptors for ACh: nicotinic and muscarinic, so called because the alkaloids nicotine and muscarine bind exclusively to and activate one or the other type of ACh receptor. The nicotinic receptor is an ionotropic receptor, whereas the muscarinic receptor is a metabotropic receptor (see Chapter 8). We shall learn more about muscarinic ACh receptors in Chapter 11.

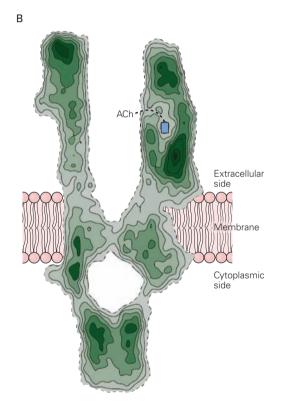

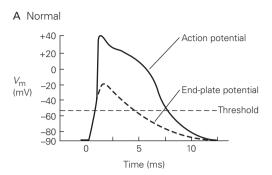

Figure 9–3 Low-resolution structure of the acetylcholine (ACh) receptor-channel. These reconstructed electron microscope images were obtained by computer processing of negatively stained images of ACh receptors in the fish *Torpedo californica*. The resolution is fine enough to see overall structures but too coarse to resolve individual atoms.

A. View looking down on the receptor from the extracellular space. The overall diameter of the receptor and its channel is approximately 8.5 nm. (Reproduced, with permission, from Brisson and Unwin 1985.)

B. Side view of the receptor in the lipid bilayer. The pore is wide at the external and internal surfaces of the membrane but narrows considerably within the lipid bilayer. The channel extends some distance into the extracellular space. A molecule of ACh enters a crevice in the wall of the receptor. (Adapted, with permission, from Karlin 2002; Miyazawa et al. 1999.)

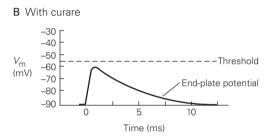

Figure 9-4 The end-plate potential can be isolated pharmacologically for study.

A. Under normal circumstances stimulation of the motor axon produces an action potential in a skeletal muscle cell. The **dashed line** shows the inferred time course of the end-plate potential that triggers the action potential.

B. Curare blocks the binding of acetylcholine (ACh) to its receptor and so prevents the end-plate potential from reaching the threshold for an action potential (dashed line). In this way the currents and channels that contribute to the end-plate potential, which are different from those producing an action potential, can be studied. The end-plate potential shown here was recorded in the presence of a low concentration of curare, which blocks only a fraction of the ACh receptors. The values for the resting potential (–90 mV), end-plate potential, and action potential in these intracellular recordings are typical of a vertebrate skeletal muscle.

The End-Plate Potential Is Produced by Ionic Current Through Acetylcholine Receptor-Channels

The end-plate potential was first studied in detail in the 1950s by Paul Fatt and Bernard Katz using intracellular voltage recordings. Fatt and Katz were able to isolate the end-plate potential by applying the drug curare² to reduce the amplitude of the postsynaptic potential below the threshold for the action potential (Figure 9–4). They found that the EPSP in muscle cells

²Curare is a mixture of plant toxins used by South American Indians, who apply it to arrowheads to paralyze their quarry. Tubocurarine, the purified active agent, blocks neuromuscular transmission by binding to the nicotinic ACh receptor, preventing its activation by ACh.

was largest at the end-plate and decreased progressively with distance (Figure 9–5).

From this, Fatt and Katz concluded that the endplate potential is generated by an inward ionic current that is confined to the end-plate and then spreads passively away. (Remember, an inward current corresponds to an influx of positive charge, which depolarizes the inside of the membrane.) Inward current is confined to the end-plate because the ACh receptorchannels are concentrated there, opposite the presynaptic terminal from which transmitter is released.

The end-plate potential rises rapidly but decays more slowly. The rapid rise is caused by the sudden release into the synaptic cleft of ACh, which diffuses rapidly to the receptors at the end-plate. (Not all the ACh reaches receptors, however, because ACh is quickly removed from the synaptic cleft by hydrolysis by acetylcholinesterase and diffusion.)

The current that generates the end-plate potential was first studied in voltage-clamp experiments (see Box 7–1). These studies revealed that the end-plate current rises and decays more rapidly than the resultant end-plate potential (Figure 9–6). The time course of the end-plate current is directly determined by the rapid opening and closing of the ACh receptor-channels. Because it takes time for an ionic current to charge or discharge the muscle membrane capacitance, and thus alter the membrane voltage, the EPSP lags behind the

synaptic current (see Figure 6–15 and the Postscript at the end of this chapter).

The Ion Channel at the End-Plate Is Permeable to Both Sodium and Potassium

Why does the opening of the ACh receptor-channels lead to an inward current that produces the depolarizing end-plate potential? And which ions move through the ACh-gated channels to produce this inward current? One important means of identifying the ion (or ions) responsible for the synaptic current is to measure the value of the chemical driving force (the chemical battery) propelling ions through the channel. Remember, the current through a set of membrane channels is given by the product of the membrane conductance and the electrochemical driving force on the ions conducted through the channels (see Chapter 6). The end-plate current that underlies the EPSP is determined by:

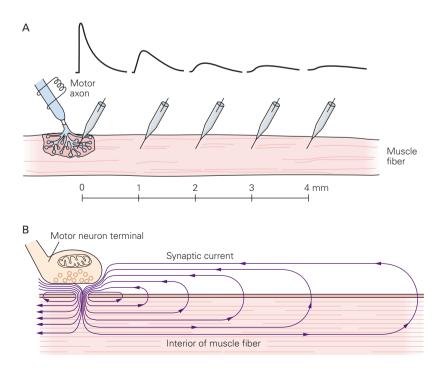

$$I_{\text{EPSP}} = g_{\text{EPSP}} \times (V_{\text{m}} - E_{\text{EPSP}}), \tag{9-1}$$

where I_{EPSP} is the end-plate current, g_{EPSP} is the conductance of the ACh receptor-channels, V_{m} is the membrane potential, and E_{EPSP} is the chemical driving force or battery generated by the transmembrane concentration gradients of the ions conducted through the channels.

Figure 9–5 The end-plate potential decreases with distance as it passively propagates away from the end-plate. (Adapted, with permission, from Miles 1969.)

A. The amplitude of the postsynaptic potential decreases and the time course of the potential slows with distance from the site of initiation in the end-plate.

B. The decay results from leakiness of the muscle fiber membrane. Because charge must flow in a complete circuit, the inward synaptic current at the end-plate gives rise to a return outward current through resting channels and across the membrane (the capacitor). This return outward flow of positive charge depolarizes the membrane. Because current leaks out all along the membrane, the outward current decreases with distance from the end-plate.

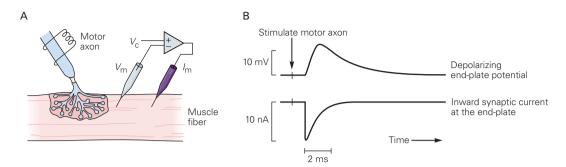

Figure 9–6 The end-plate current increases and decays more rapidly than the end-plate potential.

A. The membrane at the end-plate is voltage-clamped by inserting two microelectrodes into the muscle at the end-plate. One electrode measures membrane potential (V_m) and the second passes current (I_m) . Both electrodes are connected to a negative feedback amplifier, which ensures that sufficient current (I_m) is delivered so that V_m will remain clamped at the command potential V_c . The synaptic current evoked by stimulating the

motor nerve can then be measured at constant $V_{\rm m}$, for example $-90~{\rm mV}$ (see Box 7–1).

B. The end-plate potential (measured when $V_{\rm m}$ is not clamped) changes relatively slowly and lags behind the more rapid inward synaptic current (measured under voltage-clamp conditions). This is because synaptic current must first alter the charge on the membrane capacitance of the muscle before the muscle membrane is depolarized.

The fact that current through the end-plate is inward at the normal resting potential of a muscle cell (-90 mV) indicates that there is an inward (negative) electrochemical driving force on the ions that carry current through the ACh receptor-channels at this potential. Thus, $E_{\rm EPSP}$ must be positive to -90 mV.

The value of E_{EPSP} in Equation 9–1 can be determined by altering $V_{\rm m}$ in a voltage-clamp experiment and determining its effect on I_{EPSP} . Depolarizing the membrane reduces the net inward electrochemical driving force, thus decreasing the magnitude of the inward end-plate current. If $V_{\rm m}$ is set equal to $E_{\rm EPSP}$ there will be no net current through the end-plate channels because the electrical driving force (V_m) will exactly balance the chemical driving force (E_{EPSP}). The potential at which the net ionic current is zero is the reversal potential for current through the synaptic channels; by determining the reversal potential we can experimentally measure the value of $E_{\rm EPSP}$. If $V_{\rm m}$ is made more positive than E_{EPSP} , there will be a net outward driving force. In that case stimulation of the motor nerve leads to an outward ionic current (by opening the ACh receptor-channels) that hyperpolarizes the membrane.

If an influx of Na⁺ were solely responsible for the end-plate potential, the reversal potential for the excitatory postsynaptic potential would be the same as the equilibrium potential for Na⁺ ($E_{\rm Na}$ = +55 mV). Thus, if $V_{\rm m}$ is experimentally altered from –100 to +55 mV, the end-plate current should diminish progressively because the electrochemical driving force on Na⁺ ($V_{\rm m}$ – $E_{\rm Na}$)

is reduced. At +55 mV the inward current should be abolished, and at potentials more positive than +55 mV the end-plate current should reverse in direction and become outward.

Instead, experiments at the end-plate showed that as $V_{\rm m}$ is reduced, the inward current rapidly becomes smaller and is abolished at 0 mV. At values more positive than 0 mV the end-plate current reverses direction and becomes outward (Figure 9–7). This reversal potential is not equal to the equilibrium potential for Na⁺ or any of the other major cations or anions. In fact, this chemical potential is produced not by a single ion species but by a combination of ions: The ligand-gated channels at the end-plate are almost equally permeable to both major cations, Na⁺ and K⁺. Thus, during the end-plate potential Na⁺ flows into the cell and K⁺ flows out. The reversal potential is at 0 mV because this is a weighted average of the equilibrium potentials for Na⁺ and K⁺(Box 9–1). At the reversal potential the influx of Na⁺ is balanced by an equal efflux of K⁺ (Figure 9–7).

Why are the ACh receptor-channels at the endplate not selective for a single ion species like the voltage-gated Na⁺ or K⁺ channels? This is because the diameter of the pore of the ACh receptor-channel is substantially larger than that of the voltage-gated channels. Electrophysiological measurements suggest that it may be up to 0.8 nm in diameter, an estimate based on the size of the largest organic cation that can permeate the channel. For example, the permeant cation tetramethylammonium (TMA) is approximately 0.6 nm in diameter. In contrast, the voltage-gated Na⁺ channel is only permeant to organic cations that are smaller than 0.5×0.3 nm in cross section, and voltage-gated K^+ channels will only conduct ions less than 0.3 nm in diameter.

The relatively large diameter of the ACh receptor pore is thought to provide a water-filled environment that allows cations to diffuse through the channel relatively unimpeded, much as they would in free solution. This explains why the pore does not discriminate between Na⁺ and K⁺. It also explains why even divalent cations, such as Ca²⁺, can permeate the channel. Anions are excluded, however, by the presence of fixed negative charges in the channel, as described later in this chapter.

The Current Through Single Acetylcholine Receptor-Channels Can Be Measured Using the Patch Clamp

The synaptic current at the end-plate is generated by a couple of hundred thousand channels. Recordings of the current through single ACh receptor-channels, using the patch-clamp technique (see Box 5–1), have provided us with insight into the molecular events underlying the end-plate potential.

Individual Receptor-Channels Conduct All-or-None Unitary Currents

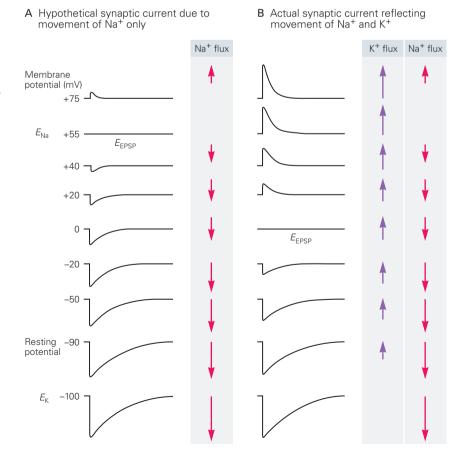

The first successful recordings of single ACh receptorchannel currents from skeletal muscle cells, by Erwin Neher and Bert Sakmann in 1976, showed that the opening of an individual channel generates a very small rectangular step of ionic current (Figure 9–8). At a given resting potential a channel will always generate the same-size current pulse. At –90 mV the current steps are approximately –2.7 pA in amplitude. Although this is a very small current, it corresponds to a flow of approximately 17 million ions per second!

The current steps change in size with changes in membrane potential because the current depends on

Figure 9-7 The end-plate potential is produced by the simultaneous flow of Na⁺ and K⁺ through the same receptor-channels. The ionic currents responsible for the end-plate potential can be determined by measuring the reversal potential of the end-plate current using a voltage clamp.

A. In the hypothetical case in which Na⁺ flux alone is responsible for the end-plate current, the reversal potential would occur at +55 mV, the equilibrium potential for Na⁺ ($E_{\rm Na}$). The arrow at the right of each current record reflects the magnitude of the net Na⁺ flux at that membrane potential. (Down arrows = inward; up arrows = outward).

B. In the actual case in which the ACh receptor-channel is permeable to both Na $^+$ and K $^+$, experimental results show that the end-plate current reverses at 0 mV because the ion channel allows Na $^+$ and K $^+$ to move into and out of the cell simultaneously (see Box 9–1). The net current is the sum of the Na $^+$ and K $^+$ fluxes through the end-plate channels. At the reversal potential (E_{EPSP}) the inward Na $^+$ flux is balanced by an outward K $^+$ flux so that no net charge flows.

Box 9–1 Reversal Potential of the End-Plate Potential

The reversal potential of a membrane current carried by more than one ion species, such as the end-plate current through the ACh receptor-channel, is determined by two factors: (1) the relative conductance for the permeant ions (g_{Na} and g_{K} in the case of the end-plate current) and (2) the equilibrium potentials of the ions (E_{Na} and E_{K}).

At the reversal potential for the ACh-gated current, inward current carried by Na^+ is balanced by outward current carried by K^+ :

$$I_{\text{Na}} + I_{\text{K}} = 0.$$
 (9–2)

The individual Na⁺ and K⁺ currents can be obtained from

$$I_{\text{Na}} = g_{\text{Na}} \times (V_{\text{m}} - E_{\text{Na}}) \tag{9-3a}$$

and

$$I_{\rm K} = g_{\rm K} \times (V_{\rm m} - E_{\rm K}).$$
 (9–3b)

Remember that these currents do not result from Na⁺ and K⁺ flowing through separate channels (as occurs during the action potential) but through the same ACh receptor-channel. We can substitute Equations 9–3a and 9–3b for $I_{\rm Na}$ and $I_{\rm K}$ in Equation 9–2, replacing $V_{\rm m}$ with $E_{\rm EPSP}$ (because at the reversal potential $V_{\rm m} = E_{\rm EPSP}$):

$$g_{\text{Na}} \times (E_{\text{EPSP}} - E_{\text{Na}}) + g_{\text{K}} \times (E_{\text{EPSP}} - E_{\text{K}}) = 0.$$
 (9-4)

Solving this equation for E_{EPSP} yields

$$E_{\text{EPSP}} = \frac{(g_{\text{Na}} \times E_{\text{Na}}) + (g_{\text{K}} \times E_{\text{K}})}{g_{\text{Na}} + g_{\text{K}}}.$$
 (9-5)

If we divide the top and bottom of the right side of this equation by $g_{K'}$ we obtain

$$E_{\text{EPSP}} = \frac{E_{\text{Na}} (g_{\text{Na}}/g_{\text{K}}) + E_{\text{K}}}{(g_{\text{Na}}/g_{\text{K}}) + 1} \cdot$$
 (9-6)

If $g_{Na} = g_K$, then $E_{EPSP} = (E_{Na} + E_K)/2$.

These equations can also be used to solve for the ratio $g_{\text{Na}}/g_{\text{K}}$ if one knows E_{EPSP} , E_{K} , and E_{Na} . Thus, rearranging Equation 9–6 yields

$$\frac{g_{\text{Na}}}{g_{\text{K}}} = \frac{E_{\text{EPSP}} - E_{\text{K}}}{E_{\text{Na}} - E_{\text{EPSP}}}.$$
 (9–7)

At the neuromuscular junction, $E_{\rm EPSP}=0$ mV, $E_{\rm K}=-100$ mV, and $E_{\rm Na}=+55$ mV. Thus, from Equation 9–7, $g_{\rm Na}/g_{\rm K}$ has a value of approximately 1.8, indicating that the conductance of the ACh receptor-channel for Na⁺ is slightly higher than for K⁺. A comparable approach can be used to analyze the reversal potential and the movement of ions during excitatory and inhibitory synaptic potentials in central neurons (see Chapter 10).

the electrochemical driving force ($V_{\rm m}$ – $E_{\rm EPSP}$). For single ion channels the equivalent of Equation 9–1 is

$$i_{\text{EPSP}} = \gamma_{\text{EPSP}} \times (V_{\text{m}} - E_{\text{EPSP}}),$$

where $i_{\rm EPSP}$ is the amplitude of current through one channel and $\gamma_{\rm EPSP}$ is the conductance of a single channel. The relationship between $i_{\rm EPSP}$ and membrane voltage is linear, indicating that the single-channel conductance is constant and does not depend on membrane voltage; that is, the channel behaves as a simple resistor. From the slope of this relation the channel is found to have a conductance of 30 pS. The reversal potential of 0 mV, obtained from the intercept of the membrane voltage axis, is identical to that for the end-plate current (Figure 9–9B).

Although the amplitude of the current through a single ACh channel is constant for every opening, the

duration of each opening and the time between openings vary considerably. These variations occur because channel openings and closings are stochastic; they obey the same statistical law that describes radioactive decay. Because of the random thermal motions and fluctuations that a channel experiences, it is impossible to predict exactly how long it will take any one channel to bind ACh or how long that channel will stay open before the ACh dissociates and the channel closes. However, the average length of time a particular type of channel stays open is a well-defined property of that channel, just as the half-life of radioactive decay is an invariant property of a particular isotope. The mean open time for ACh receptor-channels is approximately 1 ms. Thus each channel opening permits the movement of approximately 17,000 ions.

Figure 9–8 Individual ACh receptorchannels conduct an all-or-none elementary current.

A. The patch-clamp technique is used to record currents from single ACh receptor-channels. The patch electrode is filled with salt solution that contains a low concentration of ACh and is then brought into close contact with the surface of the muscle membrane (see Box 5–1). The patch may contain one or many receptor-channels.

B. Single-channel currents from a patch of frog muscle membrane with a resting potential of -90 mV were recorded in the presence of 100 nM ACh. (1) The opening of a channel results in an influx of positive charge (recorded as a downward current step). The patch contained a large number of ACh receptorchannels so that successive openings in the record probably arise from different channels. (2) A histogram plotting the amplitudes of these rectangular pulses (in pA) versus the number of observed pulses with the given amplitude. The histogram has a single peak, indicating that the patch of membrane contains only a single type of active channel with an elementary current that varies randomly around a mean of -2.7 pA (1 pA = 10^{-12} A). This mean, the *elemen*tary current, represents an elementary conductance of 30 pS. (Reproduced, with permission, from B. Sakmann.)

C. When the membrane potential is increased to -130 mV, the individual channel currents increase to -3.9 pA because of the increase in electrical driving force. The elementary conductance remains equal to 30 pS. When several channels open simultaneously, the individual current pulses add linearly. The record shows one, two, or three channels open at different times in response to application of ACh. (Reproduced, with permission, from B. Sakmann.)

Α

C Total ionic current in a patch of membrane

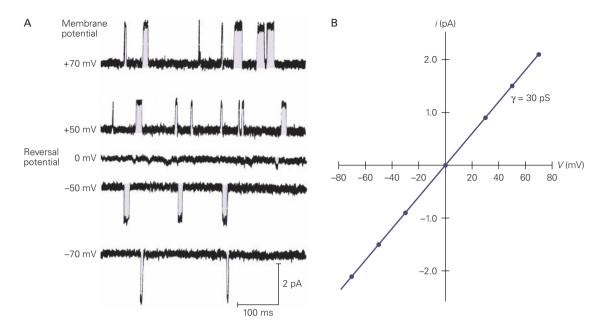

Figure 9–9 The ACh receptor-channel behaves as a simple resistor.

A. The voltage across a patch of membrane was systematically varied during exposure to 2 μM ACh. The current recorded at the patch is inward at voltages negative to 0 mV and outward at voltages positive to 0 mV, thus defining 0 mV as the reversal potential.

B. The linear relation between current through a single ACh receptor-channel and membrane voltage shows that the channel behaves as a simple resistor with a single-channel conductance (γ) of about 30 pS.

Each ACh receptor-channel has two binding sites for ACh; both sites must be occupied by transmitter for the channel to open efficiently. Once a channel closes, the ACh molecules dissociate and the channel remains closed until it binds ACh again.

Four Factors Determine the End-Plate Current

Stimulation of a motor nerve releases a large quantity of ACh into the synaptic cleft. The ACh rapidly diffuses across the cleft and binds to the ACh receptors, causing more than 200,000 receptor-channels to open almost simultaneously. (This number is obtained by comparing the total end-plate current, approximately –500 nA, with the current through a single channel, approximately –2.7 pA.) How do small step-like changes in current through 200,000 individual ACh receptor-channels produce the smooth waveform of the end-plate current?

The rapid opening of so many channels causes a large increase in the total conductance of the end-plate membrane, $g_{\rm EPSP}$, and produces the rapid increase in end-plate current. The ACh in the cleft decreases rapidly to zero (in less than 1 ms) because of enzymatic hydrolysis and diffusion, after which the channels begin to close

in the random manner described above. Each closure produces a small step-like decrease in end-plate current because of the all-or-none nature of single-channel currents. However, because each unitary current step is tiny relative to the large current carried by many thousands of channels, the random closing of a large number of small unitary currents causes the total end-plate current to appear to decay smoothly (Figure 9–10).

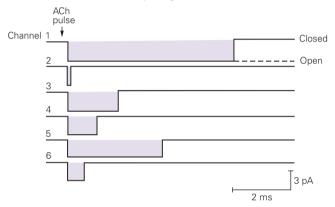

The summed conductance of all open channels in a large population of ACh receptor-channels is the total synaptic conductance, $g_{\text{EPSP}} = n \times \gamma$, where n is the average number of channels opened and γ is the conductance of a single channel. The number of open channels is the product of the total number of channels in the end-plate membrane (N) and the probability that any given channel is open, $n = N \times p_{\text{open}}$. The probability that a channel is open depends largely on the concentration of the transmitter at the receptor, not on the value of the membrane potential, because the channels are opened by the binding of ACh, not by voltage. The total end-plate current is therefore given by

$$I_{\text{EPSP}} = N \times p_{\text{open}} \times \gamma \times (V_{\text{m}} - E_{\text{EPSP}}),$$
$$= n \times \gamma \times (V_{\text{m}} - E_{\text{EPSP}}).$$

This equation shows that the total end-plate current depends on four factors: (1) the total number of end-plate channels (N); (2) the probability that a channel is open ($p_{\rm open}$); (3) the conductance of each open channel (γ); and (4) the driving force on the ions ($V_{\rm m} - E_{\rm EPSP}$).

The relationships between total end-plate current, end-plate potential, and single-channel current are

A Idealized time course of opening of six ion channels

B Total current of the six channels

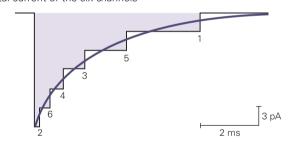

Figure 9–10 The time course of the total current at the end-plate results from the summed contributions of many individual ACh receptor-channels. (Reproduced, with permission, from Colquhoun 1981.)

A. Individual ACh receptor-channels open in response to a brief pulse of ACh. In this idealized example the membrane contains a total of six ACh receptor-channels. All channels open rapidly and nearly simultaneously. The channels remain open for varying times and close independently.

B. The stepped trace shows the sum of the six single-channel current records in part A. It represents the current during the sequential closing of each channel (the number indicates which channel has closed) in a hypothetical end-plate containing only six channels. In the final period of current only channel 1 is open. In a current record from a whole muscle fiber, with thousands of channels, the individual channel closings are not visible because the current scale needed to display the total end-plate current (hundreds of nanoamperes) is so large that the contributions of individual channels cannot be resolved. As a result, the total end-plate current appears to decay smoothly.

shown in Figure 9–11 for a wide range of membrane potentials.

The Molecular Properties of the Acetylcholine Receptor-Channel Are Known

The ACh receptors that produce the end-plate potential differ in two important ways from the voltage-gated channels that generate the action potential in muscle. First, the action potential is generated by two distinct classes of voltage-gated channels that are activated sequentially, one selective for Na⁺ and the other for K⁺. In contrast, the ACh receptor-channel alone generates the end-plate potential by allowing both Na⁺ and K⁺ to pass with nearly equal permeability.

Second, the Na⁺ flux through voltage-gated channels is regenerative: By increasing the depolarization of the cell, the Na⁺ influx opens more voltage-gated Na⁺ channels. This regenerative feature is responsible for the all-or-none property of the action potential. In contrast, the number of ACh receptor-channels opened during the synaptic potential is fixed by the amount of ACh available. The depolarization produced by Na⁺ influx through these ligand-gated channels does not lead to the opening of more ACh-gated channels and cannot produce an action potential. To trigger an action potential, a synaptic potential must recruit neighboring voltage-gated channels (Figure 9–12).

As might be expected from these two differences in physiological properties, the ACh-gated and voltage-gated channels are formed by different macromolecules that exhibit different sensitivities to drugs and toxins. Tetrodotoxin, which blocks the voltage-gated Na $^+$ channel, does not block the influx of Na $^+$ through the nicotinic ACh receptor-channels. Similarly, α -bungarotoxin, a snake venom protein that binds tightly to the nicotinic receptors and blocks the action of ACh, does not interfere with voltage-gated Na $^+$ or K $^+$ channels (α -bungarotoxin has proved useful in the biochemical characterization of the ACh receptor).

The nicotinic ACh receptor at the nerve-muscle synapse is an ionotropic receptor: It is part of a single macromolecule that includes the pore in the membrane through which ions flow. Where in the molecule is the binding site located? How is the pore of the channel formed? What are its properties? Insights into these questions have been obtained from molecular studies of the ACh receptor proteins and their genes.

Biochemical studies by Arthur Karlin and Jean-Pierre Changeux indicate that the mature nicotinic ACh receptor is a membrane glycoprotein formed from five subunits: two α -subunits and one β -, one γ -,

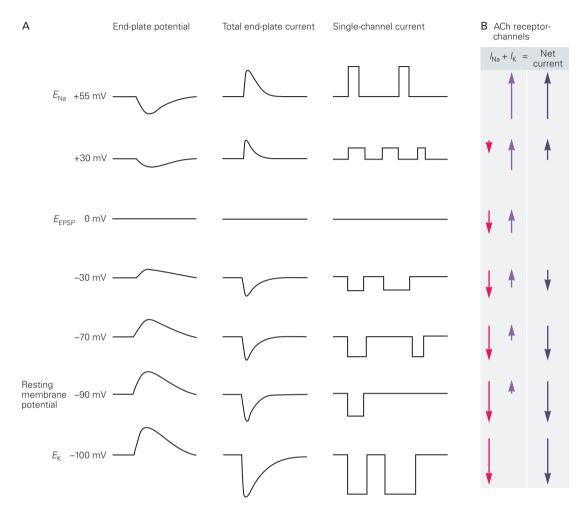

Figure 9–11 Membrane potential has a similar effect on the end-plate potential, total end-plate current, and ACh-gated single-channel current.

A. At the normal resting potential of the muscle membrane (–90 mV) the current through single ACh receptor-channels is large and inward because of the large inward driving force on Na⁺ and small outward driving force on K⁺. The resulting total end-plate current (made up of currents from more than 200,0000 channels) produces a large depolarizing end-plate potential. At more positive levels of membrane potential (increased depolarization), the inward driving force on Na⁺ is less and the outward driving force on K⁺ is greater. This results in a decrease in the size of the single-channel and total end-plate current, thus reducing the size of the end-plate potential.

At the reversal potential (0 mV) the inward Na $^+$ flux is balanced by the outward K $^+$ flux, so there is no net current at the end-plate and no change in $V_{\rm m}$. Further depolarization to +30 mV inverts the direction of the end-plate current, as there is now a much larger outward driving force on K $^+$ and a small inward driving force on Na $^+$. As a result, the outward flow of K $^+$ hyperpolarizes the membrane. Note that on either side of the reversal potential the end-plate current drives the membrane potential toward the reversal potential.

B. The direction of Na⁺and K⁺ fluxes in individual channels changes with $V_{\rm m}$. The algebraic sum of the Na⁺and K⁺ currents, $I_{\rm Na}$ and $I_{\rm K}$, gives the *net current* through the ACh receptor-channels. (Arrow length represents the relative magnitude of a current. Up = out, down = in.)

and one δ -subunit. The amino terminus of each of the subunits is exposed on the extracellular surface of the membrane and contains the ACh-binding site. Karlin and his colleagues have identified two extracellular binding sites for ACh on each receptor-channel in the clefts between each α -subunit and its neighboring γ - or

 δ -subunit. One molecule of ACh must bind at each of the two sites for the channel to open efficiently (Figure 9–13). The inhibitory snake venom α -bungarotoxin also binds to the ACh-binding sites on the α -subunit.

Insight into the structure of the channel has come from analysis of the primary amino acid sequences

of the receptor's subunits as well as from biophysical studies. The work of Shosaku Numa and his colleagues demonstrated that the four subunit types are encoded by distinct but related genes. Sequence comparison of the subunits shows a high degree of similarity among them: One-half of the amino acid residues are identical or conservatively substituted. This similarity suggests that all subunits have a similar structure. Furthermore, all four of the genes for the subunits are homologous; that is, they are derived from a common ancestral gene.

The distribution of the polar and nonpolar amino acids of the subunits provides important clues as to how the subunits are threaded through the membrane bilayer. Each subunit contains four hydrophobic regions of approximately 20 amino acids called M1 to M4, each of which is thought to form an α -helix that spans the membrane. The amino acid sequences of the subunits suggest that the subunits are symmetrically arranged like the staves of a barrel, creating a central pore through the membrane (Figure 9–14).

The walls of the channel pore are formed by the M2 membrane-spanning segment and by the loop

connecting M2 to M3. Three rings of negative charges that flank the external and internal boundaries of the M2 segment play an important role in the channel's selectivity for cations. Certain local anesthetic drugs block the channel by interacting with one ring of polar serine residues and two rings of hydrophobic residues in the central region of the M2 helix, midway through the membrane (Figure 9–14D).

A three-dimensional model of the entire receptorchannel complex has been proposed by Arthur Karlin and Nigel Unwin based on neutron scattering and electron diffraction images respectively (see Figure 9–3). The complex is divided into three regions: a large extracellular portion that contains the ACh binding site, a narrow transmembrane pore selective for cations, and a large exit region at the internal membrane surface (Figure 9–14C). The extracellular region is surprisingly large, approximately 6 nm in length. In addition, the extracellular end of the pore has a wide mouth approximately 2.5 nm in diameter. Within the bilayer of the membrane the pore gradually narrows.

More detailed insight into the structure of the extracellular domain of the ACh receptor has come

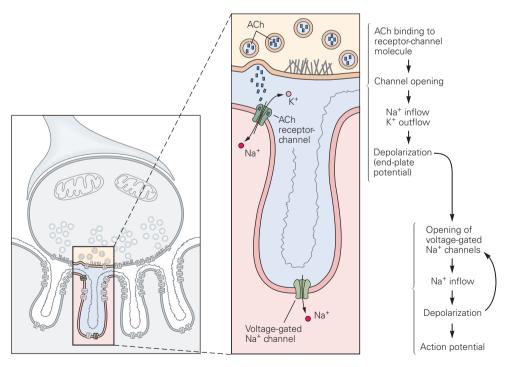

Figure 9–12 The depolarization resulting from the opening of ACh receptor-channels at the end-plate opens voltage-gated Na⁺ channels. The depolarization of the muscle membrane during the end-plate potential opens neighboring

voltage-gated Na⁺ channels in the muscle membrane. The depolarization is normally large enough to open a sufficient number of Na⁺ channels to exceed the threshold for an action potential. (Reproduced, with permission, from Alberts et al. 1989.)

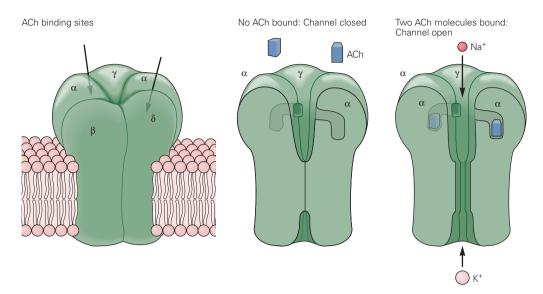

Figure 9–13 The nicotinic ACh receptor-channel is a pentameric macromolecule. The receptor-channel is a single macromolecule consisting of five subunits, which form a pore through the cell membrane (see Figure 9–14). The channel is composed of two identical α -subunits, and one each of the β -, γ -, and δ -subunits. When two molecules of ACh bind to the

extracellular binding sites—formed at the interfaces of the two α -subunits and their neighboring γ - and δ -subunits—the receptor-channel molecule changes conformation. This change opens the pore through which both K⁺ and Na⁺ flow down their electrochemical gradients.

from X-ray crystallographic studies of a molluscan ACh-binding protein, which is homologous to the amino terminus of the nicotinic ACh receptor sub-unit at the end-plate. Remarkably, unlike typical ACh receptors, the molluscan ACh-binding protein is a soluble protein secreted by glial cells into the extracellular space. At cholinergic synapses in snails it acts to reduce the size of the excitatory postsynaptic potential, perhaps by buffering the free concentration of ACh in the synaptic cleft.

In a crystal structure of the molluscan AChbinding protein in the presence of nicotine, five identical subunits are assembled into a symmetric pentameric ring (Figure 9-15A). The walls of the protein are seen to surround a large vestibule, which presumably funnels ions toward the narrow transmembrane domain of the receptor. Each subunit binds one molecule of nicotine at the ACh binding site, which is located at the interface between neighboring subunits; thus, the pentamer binds a total of five molecules of ligand. Although nicotinic ACh receptors at the end-plate have only two binding sites for ligand, some neuronal nicotinic ACh receptors are composed of five identical subunits and are thought to bind five molecules of ACh. Although the overall similarity of the amino acid sequences of the molluscan protein and nicotinic ACh receptors is fairly low (25%), the residues that form the

ACh binding site are highly conserved, suggesting that the structure of the site is similar to that of the molluscan protein.

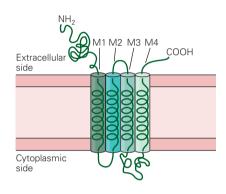

Our picture of the transmembrane region of the nicotinic ACh receptor is still incomplete. However, recent electron diffraction data from Unwin suggest that the four transmembrane segments of each subunit are indeed α -helixes that traverse the 3 nm length of the lipid bilayer (Figure 9–15B). The pore-lining M2 segments are inclined toward the central axis of the channel, so that the pore narrows continuously from the outside of the membrane to the inside. In the closed state a ring of hydrophobic residues is thought to constrict the pore in the middle of the M2 helix to a diameter of less than 0.6 nm. This hydrophobic ring may act as the channel's gate, providing a steric and energetic barrier that prevents ion conduction.

The binding of ACh to the receptor is thought to trigger a rotation of the extracellular binding domain that is somehow coupled to an opposite rotation in the M2 helixes, widening the constriction in the middle of M2 to around 0.8 to 0.9 nm, enabling ion permeation. This diameter is in reasonable agreement with electrophysiological estimates based on the pore's permeability to organic cations. The work of Karlin, however, suggests that the gate lies near the cytoplasmic mouth of the channel.

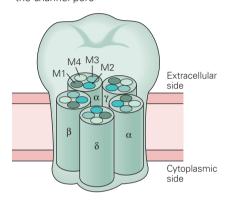

An Overall View

The terminals of motor neurons form synapses with muscle fibers at specialized regions in the muscle membrane called end-plates. When an action potential reaches the terminals of a presynaptic motor neuron it causes release of ACh. The transmitter diffuses across the synaptic cleft and binds to nicotinic ACh receptors in the end-plate, thus opening channels that allow Na^+ , K^+ , and Ca^{2+} to flow across the postsynaptic muscle. A net influx of Na^+ ions produces a depolarizing synaptic potential called the end-plate potential.

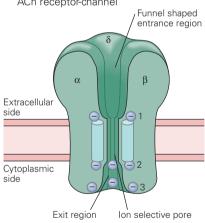

B Arrangement of subunits surrounding the channel pore

C Functional model of ACh receptor-channel

D Amino acid sequence of channel subunits

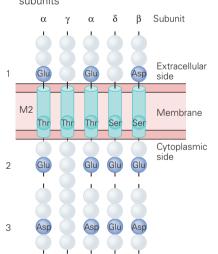

Figure 9–14 The ACh receptor subunits are homologous membrane-spanning proteins.

A. Each subunit contains a large extracellular N-terminus, four membrane-spanning α -helixes (M1–M4), and a short extracellular C-terminus. The N-terminus contains the ACh-binding site, and the membrane helixes form the pore.

B. The five subunits are arranged such that they form a central aqueous channel, with the M2 segment of each subunit forming the lining of the pore. Note that the γ -subunit lies between the two α -subunits. (Dimensions are not to scale.)

C. According to one model, negatively charged amino acids on each subunit form three rings of negative charge around the

pore. As an ion traverses the channel it encounters these rings of charge. The rings at the external (1) and internal (3) surfaces of the cell membrane may serve as prefilters that help repel anions and form divalent cation blocking sites. The central ring near the cytoplasmic side of the membrane bilayer (2) may contribute more importantly to establishing the specific cation selectivity of the selectivity filter, which is the narrowest region of the pore.

D. The amino acid sequences of the M2 and flanking regions of each of the five subunits. The horizontal series of amino acids numbered 1, 2, and 3 constitute the three rings of negative charge (part C). The aligned serine and threonine residues within M2 help form the selectivity filter.

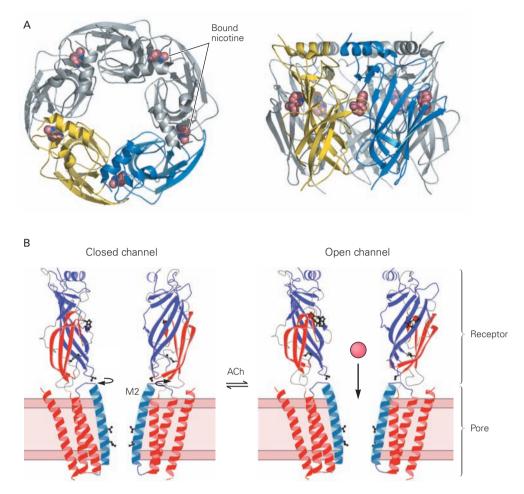

Figure 9–15 A high-resolution three-dimensional structural model of the nicotinic ACh receptor-channel.

A. A structural model of the ACh-binding protein, secreted by glial cells in mollusks, in the presence of nicotine. Five identical subunits assemble into a pentameric macromolecule that contains a large central cavity. The ACh-binding protein is homologous to the extracellular ligand-binding domain of the ACh receptor-channel, which is thus thought to resemble this structure. The view on the left shows the ACh-binding protein in an orientation that corresponds to looking down at the ACh receptor-channel from the extracellular side of the membrane. The view on the right shows the ACh-binding protein in an orientation that corresponds to looking at the side of the extracellular portion of the ACh receptor-channel with the membrane below. (Reproduced, with permission, from Celie et al. 2004.)

B. A model for the ACh-receptor channel in the open and closed states. View looking at the side of the channel, showing two of five subunits. The structure of the extracellular region is based on the structure of the ACh-binding protein. The structure of the membrane helixes is based on electron diffraction analysis of two-dimensional crystals of the ACh receptor-channel from electric fish. The M2 helixes line the pore (see Figure 9–14B). In the closed channel (left) a hydrophobic girdle of leucine and valine residues constricts the pore, preventing ion permeation. The channel opens (right) when ACh binding induces a rotation in the extracellular binding domain that leads to a corresponding rotation in the M2 helix, widening the pore and permitting ion permeation. (Reproduced, with permission, from Unwin 2003.)

Because the ACh-activated channels are concentrated at the end-plate, the opening of these channels produces only a local depolarization that spreads passively along the muscle fibers. However, this local depolarization is very large. In a healthy individual it is always suprathreshold. Thus the local depolarization activates a sufficient number of voltage-gated Na⁺

channels in the end-plate to generate an action potential that actively propagates along the length of the muscle.

The protein that forms the nicotinic ACh receptor-channel has been purified, its genes cloned, and its amino acids sequenced. It is composed of five subunits, two of which—the α-subunits that recognize and bind ACh—are identical. Each subunit has

four hydrophobic regions that are thought to form membrane-spanning α -helixes. The protein also contains two sites for recognizing and binding ACh. This channel is thus gated directly by a chemical transmitter. The functional molecular domains of the ACh receptor have been identified, and the steps that link ACh-binding to the opening of the channel are now being investigated. Although the atomic-level structure of the ACh receptor-channel has not been resolved, the structures of bacterial ligand-gated channels that are closely related to the ACh receptor have been resolved. Thus we may soon be able to see in atomic detail the molecular dynamics of the ACh receptor-channel's physiological functions.

The large number of ACh receptor-channels at the end-plate ensures that synaptic transmission will proceed with a high safety factor. In the autoimmune disease myasthenia gravis, antibodies to the ACh receptor decrease the number of ACh receptors, thus seriously compromising transmission at the neuromuscular junction (see Chapter 14). Certain congenital mutations in the ACh receptor subunits also contribute to a family of diseases of the neuromuscular junction termed congenital myasthenic syndrome. In some instances these mutations shorten the duration of channel opening, decreasing current during an excitatory postsynaptic potential. Other mutations prolong the opening of the ACh receptor-channels (slow channel syndrome). This leads to excessive Ca²⁺ influx, which is thought to promote degeneration of the end-plate.

Acetylcholine is only one of many neurotransmitters in the nervous system, and the end-plate potential is just one example of chemical signaling. Do transmitters in the central nervous system act in the same fashion, or are other mechanisms involved? In the past such questions were virtually unanswerable because of the small size and great variety of nerve cells in the central nervous system. However, advances in experimental technique—in particular, the patch clamp—have made synaptic transmission at central synapses easier to study. Already it is clear that many neurotransmitters operate in the central nervous system much as ACh operates at the end-plate, although other transmitters produce their effects in quite different ways. Some of the many variations of synaptic transmission that characterize the central and peripheral nervous systems are discussed in the next two chapters.

Postscript: The End-Plate Current Can Be Calculated from an Equivalent Circuit

The current through a population of ACh receptorchannels can be described by Ohm's law. However, to fully describe how the electrical current generates the end-plate potential, all the resting channels in the surrounding membrane must be considered. Because channels are proteins that span the bilayer of the membrane, we must also take into consideration the capacitive properties of the membrane and the ionic batteries determined by the distribution of Na⁺ and K⁺ inside and outside the cell.

The dynamic relationship of these various components can be explained using the same rules we used in Chapter 6 to analyze the current in passive electrical devices that consist only of resistors, capacitors, and batteries. We can represent the end-plate region with an equivalent circuit that has three parallel branches: (1) one representing the synaptic current through the transmitter-gated channels; (2) one representing the return current through resting channels (the non-synaptic membrane); and (3) one representing current across the lipid bilayer, which acts as a capacitor (Figure 9–16).

Because the end-plate current is carried by both Na⁺ and K⁺, we could represent the synaptic branch of the equivalent circuit as two parallel branches, each representing the flow of a different ion species. At the end-plate, however, Na⁺ and K⁺ flow through the same ion channel. It is therefore more convenient (and correct) to combine the Na⁺ and K⁺ current pathways into a single conductance (g_{EPSP}), representing the ACh-gated channels.

The conductance of this pathway depends on the number of channels opened, which in turn depends on the concentration of transmitter. In the absence of transmitter no channels are open, and the conductance is zero. When a presynaptic action potential causes the release of transmitter, the conductance of this pathway increases to a value of approximately 5×10^{-6} S (or a resistance of $2 \times 10^{5} \Omega$). This is about five times the conductance of the parallel branch representing the resting or leakage channels (g_1).

The end-plate conductance is in series with a battery ($E_{\rm EPSP}$), with a value given by the reversal potential for synaptic current (0 mV) (Figure 9–16). This value is the weighted algebraic sum of the Na⁺ and K⁺ equilibrium potentials (see Box 9–1).

The current during the excitatory postsynaptic potential (I_{EPSP}) is given by

$$I_{\text{EPSP}} = g_{\text{EPSP}} \times (V_{\text{m}} - E_{\text{EPSP}}).$$

Using this equation and the equivalent circuit of Figure 9–16 we can now analyze the end-plate potential in terms of ionic currents (Figure 9–17).

At the onset of the excitatory synaptic action (the dynamic phase), an inward current (I_{EPSP}) is generated

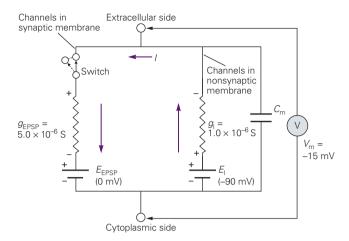

Figure 9–16 The equivalent circuit of the end-plate. The circuit has three parallel current pathways. One conductance pathway represents the end-plate current and consists of a battery, $E_{\rm EPSP}$, in series with the conductance of the ACh receptor-channels, $g_{\rm EPSP}$. Another conductance pathway represents current through the nonsynaptic membrane and consists of a battery representing the resting potential $(E_{\rm l})$ in series with the conductance of the resting channels $(g_{\rm l})$. In parallel with both of these conductance pathways is the membrane capacitance $(C_{\rm m})$. The voltmeter (V) measures the potential difference between the inside and the outside of the cell.

When no ACh is present, the end-plate channels are closed and carry no current. This state is depicted as an open electrical circuit in which the synaptic conductance is not connected to the rest of the circuit. The binding of ACh opens the synaptic channel. This event is electrically equivalent to throwing the switch that connects the gated conductance pathway (g_{EPSP}) with the resting pathway (g_{I}). In the steady state there is an inward current through the ACh-gated channels and an outward current through the resting channels. With the indicated values of conductances and batteries, the membrane will depolarize from –90 mV (its resting potential) to –15 mV (the peak of the end-plate potential).

by the ACh-gated channels because of the increased conductance to Na⁺ and K⁺ and the large inward driving force on Na⁺ at the resting potential of -90 mV (Figure 19-17B, time 2). Because charge must flow in a closed loop, the inward synaptic current must leave the cell as outward current. The equivalent circuit includes two parallel pathways for outward current: a conductance pathway (I_1) representing current through the resting (or leakage) channels and a capacitive pathway (I_2) representing current across the membrane capacitance. Thus,

$$I_{\text{EPSP}} = -(I_1 + I_c).$$

During the earliest phase of the end-plate potential the membrane potential, $V_{\rm m}$, is still close to its

resting value, E_1 . As a result, the outward driving force on current through the resting channels $(V_m - E_1)$ is small. Therefore most of the current leaves the cell as capacitive current and the membrane depolarizes rapidly (Figure 9–17B, time 2). As the cell depolarizes, the outward driving force on current through the resting channels increases, while the inward driving force on synaptic current through the ACh receptor-channels decreases. Concomitantly, as the concentration of ACh in the synapse decreases, the ACh receptor-channels begin to close, and eventually the inward current through the gated channels is exactly balanced by outward current through the resting channels $(I_{EPSP} = -I_1)$. At this point there is no current into or out of the capacitor, $(I_c = 0)$. Because the rate of change of membrane potential is directly proportional to I_c ,

$$I_c/C_m = \Delta V/\Delta t$$

the membrane potential will have reached a peak or new steady-state value, $\Delta V/\Delta t = 0$ (Figure 9–17B, time 3).

As the ACh-gated channels close, $I_{\rm EPSP}$ decreases further. Now $I_{\rm EPSP}$ and $I_{\rm l}$ are no longer in balance and the membrane potential starts to repolarize, because the outward current through leak channels ($I_{\rm l}$) becomes larger than the inward synaptic current. During most of the declining phase of the synaptic action there is no current through the ACh receptor-channels because all these channels are closed. Instead, current passes through the membrane only as outward current carried by resting channels balanced by inward current across the membrane capacitor (Figure 9–17B, time 4).

When the end-plate potential is at its peak or steady-state value, $I_{\rm c}=0$ and therefore the value of $V_{\rm m}$ can be easily calculated. The inward current through the ACh-gated channels ($I_{\rm EPSP}$) must be exactly balanced by outward current through the resting channels ($I_{\rm l}$):

$$I_{\text{EPSP}} + I_1 = 0.$$
 (9–8)

The current through the ACh receptor-channels (I_{EPSP}) and resting channels (I_{I}) is given by Ohm's law:

$$I_{\text{EPSP}} = g_{\text{EPSP}} \times (V_{\text{m}} - E_{\text{EPSP}}),$$

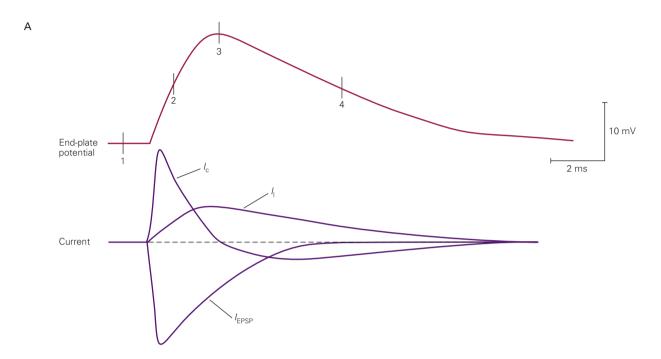

and

$$I_1 = g_1 \times (V_m - E_1).$$

By substituting these two expressions into Equation 9–8, we obtain

$$g_{\text{EPSP}} \times (V_{\text{m}} - E_{\text{EPSP}}) + g_{1} \times (V_{\text{m}} - E_{1}) = 0.$$

To solve for $V_{\rm m}$ we need only expand the two products in the equation and rearrange them so that

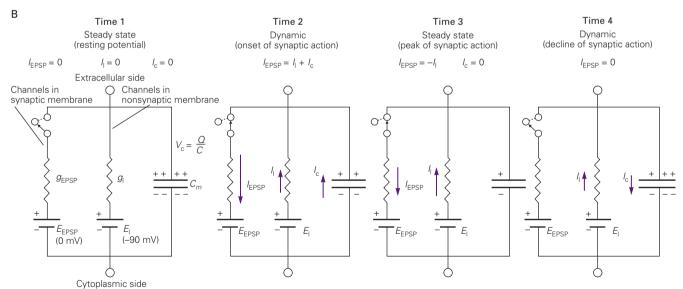

Figure 9–17 Both the ACh-gated synaptic conductance and the passive membrane properties of the muscle cell determine the time course of the end-plate potential.

A. The time course of the end-plate potential and the component currents through the ACh receptor-channels $(I_{\rm EPSP})$, the resting (or leakage) channels (I_l) , and the capacitor (I_l) . There is a capacitive current only when the membrane potential is changing. In the steady state, such as at the peak of the end-plate

potential, the inward flow of positive charge through the ACh receptor-channels is exactly balanced by the outward ionic current across the resting channels, and there is no capacitive current.

B. Equivalent circuits for the current at times 1, 2, 3, and 4 shown in part A. (The relative magnitude of a current is represented by the arrow length.)

all terms in voltage appear on the left side:

$$(g_{\text{EPSP}} \times V_{\text{m}}) + (g_{\text{l}} \times V_{\text{m}}) = (g_{\text{EPSP}} \times E_{\text{EPSP}}) + (g_{\text{l}} \times E_{\text{l}}).$$

By factoring out $V_{\rm m}$ on the left side, we finally obtain

$$V_{\rm m} = \frac{(g_{\rm EPSP} \times E_{\rm EPSP}) + (g_1 \times E_1)}{g_{\rm EPSP} + g_1}.$$
 (9-9)

This equation is similar to that used to calculate the resting and action potentials (see Chapter 6). According to Equation 9-9, the peak voltage of the end-plate potential is a weighted average of the electromotive forces of the two batteries for ACh-gated and resting currents. The weighting factors are given by the relative magnitude of the two conductances. If the ACh-gated conductance is much smaller than the resting conductance ($g_{EPSP} \ll g_1$), $g_{EPSP} \times E_{EPSP}$ will be negligible compared with $g_1 \times E_1$. Under these conditions $V_{\rm m}$ will remain close to $E_{\rm l}$. This situation occurs when only a few ACh receptor-channels are opened, because the ACh concentration is low. Conversely, if g_{EPSP} is much larger than g_1 , Equation 9–9 states that $V_{\rm m}$ approaches $E_{\rm EPSP}$, the synaptic reversal potential. This situation occurs when a large number of AChactivated channels are open, because the concentration of ACh is high. At intermediate ACh concentrations, with a moderate number of ACh-activated channels open, the peak end-plate potential lies somewhere between E_1 and E_{EPSP} .

We can now calculate the peak end-plate potential for the specific case shown in Figure 9–16, where $g_{\rm EPSP} = 5 \times 10^{-6}$ S, $g_1 = 1 \times 10^{-6}$ S, $E_{\rm EPSP} = 0$ mV, and $E_1 = -90$ mV. Substituting these values into Equation 9–9 yields

$$V_{\rm m} = \frac{[(5 \times 10^{-6} \text{ S}) \times (0 \text{ mV})] + [(1 \times 10^{-6} \text{ S}) \times (-90 \text{ mV})]}{(5 \times 10^{-6} \text{ S}) + (1 \times 10^{-6} \text{ S})}.$$

or

$$V_{\rm m} = \frac{(1 \times 10^{-6} \text{ S}) \times (-90 \text{ mV})}{(6 \times 10^{-6} \text{ S})}$$
$$= -15 \text{ mV}.$$

The peak amplitude of the end-plate potential is then

$$\Delta V_{\text{EPSP}} = V_{\text{m}} - E_{\text{l}} = -15 \text{ mV} - (-90 \text{ mV}) = 75 \text{ mV}.$$

As a check for consistency we can see whether, at the peak of the end-plate potential, the synaptic current is equal and opposite to the nonsynaptic current so that the net membrane current is indeed equal to zero:

$$I_{\text{EPSP}} = (5 \times 10^{-6} \text{ S}) \times (-15 \text{ mV} - 0 \text{ mV}) = -75 \times 10^{-9} \text{ A}$$

and

$$I_1 = (1 \times 10^{-6} \text{ S}) \times [-15 \text{ mV} - (-90 \text{ mV})] = 75 \times 10^{-9} \text{ A}.$$

Here we see that Equation 9–9 ensures that I_{EPSP} + I_1 = 0.

Synapses on a Central Neuron Are Grouped According to Physiological Function

An Overall View

IKE SYNAPTIC TRANSMISSION at the neuromuscular junction, most rapid signaling between neurons in the central nervous system involves ionotropic receptors in the postsynaptic membrane. Thus, many principles that apply to the synaptic connection between the motor neuron and skeletal muscle fiber at the neuromuscular junction also apply in the central nervous system. Synaptic transmission between central neurons is more complex, however, for several reasons. First, although most muscle fibers are innervated by only one motor neuron, a central nerve cell (such as the motor neuron in the spinal cord) receives connections from hundreds or even thousands of neurons. Second, muscle fibers receive only excitatory inputs, whereas central neurons receive both excitatory and inhibitory inputs. Third, all synaptic actions on muscle fibers are mediated by one neurotransmitter, acetylcholine (ACh), which activates only one type of receptor (the ionotropic nicotinic ACh receptor); however, a single central neuron can respond to different types of inputs, each mediated by a distinct transmitter that alters the activity of specific types of receptor. These receptors include both ionotropic receptors, where binding of transmitter directly opens an ion channel, and metabotropic receptors, where transmitter binding indirectly regulates a channel by activating second messengers. As a result, unlike muscle fibers, central neurons must integrate diverse inputs into a single coordinated action. Finally, the nerve–muscle synapse is a model of efficiency—every action potential in the motor neuron produces an action potential in the muscle fiber. In comparison, connections made by a presynaptic neuron onto the motor neuron are only modestly effective—often 50 to 100 excitatory neurons must fire together to produce a synaptic potential large enough to trigger an action potential in a motor cell.

The first insights into synaptic transmission in the central nervous system came from experiments by John Eccles and his colleagues in the 1950s on the synaptic inputs onto spinal motor neurons that control the stretch reflex, the simple behavior we considered in Chapter 2. The spinal motor neurons remain particularly useful for examining central synaptic mechanisms because they have large, accessible cell bodies and, most important, they receive both excitatory and inhibitory connections and therefore allow us to study the integrative action of the nervous system on the cellular level.

Central Neurons Receive Excitatory and Inhibitory Inputs

To analyze the synapses that mediate the stretch reflex, Eccles activated a large population of axons of the sensory cells that innervate the stretch receptor organs in the quadriceps (extensor) muscle (Figure 10–1A,B). Nowadays the same experiments can be done by stimulating a single sensory neuron. For example, passing sufficient current through a microelectrode into the cell body of a stretch-receptor neuron that innervates the extensor muscle generates an action potential in the sensory cell. This in turn produces a small excitatory postsynaptic potential (EPSP) in the motor neuron that innervates precisely the same muscle (in this case the quadriceps) monitored by the sensory neuron (Figure 10-1B upper panel). The EPSP produced by the one sensory cell, the unitary EPSP, depolarizes the extensor motor neuron by less than 1 mV, often only 0.2 to 0.4 mV, far below the threshold for generating an action potential (typically, a depolarization of 10 mV or more is required to reach threshold).

The generation of an action potential requires the near-synchronous firing of a number of sensory neurons. This can be observed in an experiment in which a population of sensory neurons is stimulated by passing current through an extracellular electrode. As the strength of the extracellular stimulus is increased, more sensory afferent fibers are excited, and the depolarization produced by the EPSP becomes larger.

The depolarization eventually becomes large enough to bring the membrane potential of the axon initial segment (the integrative component of the motor neuron) to the threshold for an action potential.

In contrast to the EPSP produced in the extensor motor neuron, stimulation of the extensor stretch-receptor neuron produces a small inhibitory post-synaptic potential (IPSP) in the motor neuron that innervates the flexor muscle, which is antagonistic to the extensor muscle (Figure 10–1B lower panels). This hyperpolarizing action is mediated by an inhibitory interneuron, which receives excitatory input from the sensory neurons of the extensor muscle and in turn makes synapses with the motor neurons that innervate the flexor muscle. In the laboratory a single interneuron can be stimulated intracellularly to directly elicit a small unitary IPSP in the motor neuron. Extracellular activation of an entire population of interneurons elicits a larger IPSP.

Although a single EPSP in the extensor motor neuron is not nearly large enough to elicit an action potential, the neuron integrates many EPSPs from a large number of afferent sensory fibers to initiate an action potential. At the same time, IPSPs, if strong enough, can counteract the sum of the excitatory actions and prevent the membrane potential from reaching threshold. In addition to counteracting synaptic excitation, synaptic inhibition can exert powerful control over action potential firing in neurons that are spontaneously active because of the presence of intrinsic pacemaker channels. This function, called the *sculpting* role of inhibition, shapes the pattern of firing in such cells (Figure 10–2).

Excitatory and Inhibitory Synapses Have Distinctive Ultrastructures

As we learned in Chapter 8, the effect of a synaptic potential—whether it is excitatory or inhibitory—is determined not by the type of transmitter released from the presynaptic neuron but by the type of ion channels in the postsynaptic cell activated by the transmitter. Although some transmitters can produce both excitatory and inhibitory postsynaptic potentials, by acting on distinct classes of ionotropic receptors at different synapses, most transmitters produce a single predominant type of synaptic response; that is, a transmitter is usually inhibitory or excitatory. For example, in the vertebrate brain neurons that release glutamate typically act on receptors that produce excitation; neurons that release γ -aminobutyric acid (GABA) or glycine act on receptors that produce inhibition.

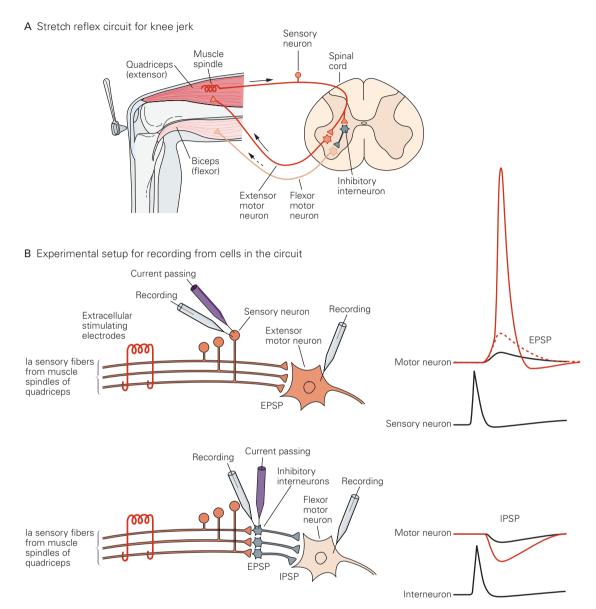

Figure 10–1 The combination of excitatory and inhibitory synaptic connections mediating the stretch reflex of the quadriceps muscle is typical of circuits in the central nervous system.

A. The stretch-receptor sensory neuron at the extensor (quadriceps) muscle makes an excitatory connection with an extensor motor neuron that innervates this same muscle group. It also makes an excitatory connection with an interneuron, which in turn makes an inhibitory connection with a flexor motor neuron that innervates the antagonist biceps femoris muscle group. Conversely, an afferent fiber from the biceps (not shown) excites an interneuron that makes an inhibitory synapse on the extensor motor neuron.

B. This idealized experimental setup shows the approaches to studying the inhibition and excitation of motor neurons in the pathway illustrated in part A. **Above:** Two alternatives for eliciting excitatory postsynaptic potentials (EPSPs) in the extensor motor neuron. A single presynaptic axon can be stimulated by

inserting a current-passing electrode into the sensory neuron cell body. An action potential in the sensory neuron stimulated in this way triggers a small EPSP in the extensor motor neuron (black trace). Alternatively, the whole afferent nerve from the quadriceps can be stimulated electrically with extracellular electrodes. The excitation of many afferent neurons through the extracellular electrode generates a synaptic potential (dashed trace) large enough to initiate an action potential (red trace). Below: The setup for eliciting and measuring inhibitory potentials in the flexor motor neuron. Intracellular stimulation of a single inhibitory interneuron receiving input from the quadriceps pathway produces a small inhibitory (hyperpolarizing) postsynaptic potential (IPSP) in the flexor motor neuron (black trace). Extracellular stimulation recruits numerous inhibitory neurons and generates a larger postsynaptic IPSP (red trace). (Action potentials from the sensory neuron and interneuron appear smaller because they were recorded at lower amplification than the motor neuron action potentials).

The synaptic terminals of excitatory and inhibitory neurons can be distinguished by their morphology. Two morphological types are common in the brain: Gray type I and type II (named after E. G. Gray, who described them). Most type I (asymmetric) synapses are glutamatergic and therefore excitatory, whereas most type II synapses (symmetric) are GABAergic and therefore inhibitory. Type I synapses have round synaptic vesicles, an electron-dense region at the active zone of the presynaptic membrane, and an even larger dense region in the postsynaptic membrane apposed to the active zone, known as the postsynaptic density (PSD). Type II synapses have oval or flattened synaptic vesicles with less obvious presynaptic membrane specializations and PSD (Figure 10–3). Although type I synapses are mostly excitatory and type II inhibitory, the two morphological types have proved to be only a first approximation to transmitter biochemistry. As we shall learn in Chapter 13, immunocytochemistry affords much more reliable distinctions between transmitter types based on the biochemical nature of the transmitters or the enzymes involved in their synthesis.

Excitatory Synaptic Transmission Is Mediated by Ionotropic Glutamate Receptor-Channels That Are Permeable to Sodium and Potassium

The excitatory transmitter released from the presynaptic terminals of stretch-receptor neurons is the amino

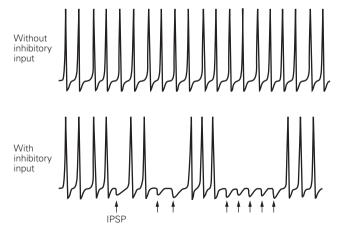

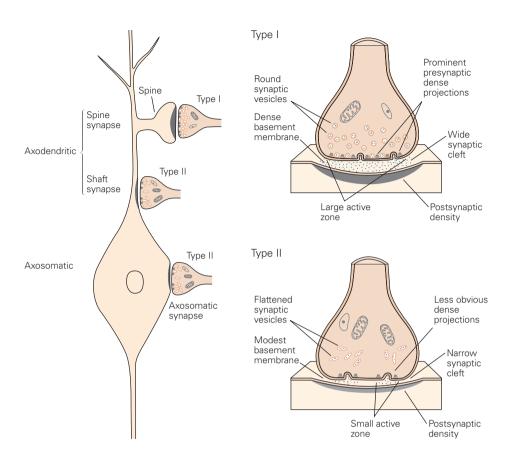

Figure 10–2 Inhibition can shape the firing pattern of a spontaneously active neuron. Without inhibitory input the neuron fires continuously at a fixed interval. With inhibitory input (arrows) some action potentials are inhibited, resulting in a distinctive pattern of impulses.

acid L-glutamate, the major excitatory transmitter in the brain and spinal cord. Eccles and his colleagues discovered that the EPSP in spinal motor cells results from the opening of glutamate-gated channels permeable to both Na⁺ and K⁺. This ionic mechanism is similar to that produced by ACh at the neuromuscular junction described in Chapter 9. Like the ACh-gated channels, the glutamate-gated channels conduct both Na⁺ and K⁺ with nearly equal permeability. As a result, the reversal potential for current flow through these channels is 0 mV (see Figure 9–7).

Glutamate receptors can be divided into two broad categories: the ionotropic receptors, which are ligandgated channels where glutamate binding directly opens the channel, and metabotropic receptors, which are G protein-coupled receptors that indirectly gate channels through the production of second messengers (Figure 10–4). There are three major subtypes of ionotropic glutamate receptors: AMPA, kainate, and NMDA, named according to the types of synthetic agonists that activate them (α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid, kainate, and N-methyl-D-aspartate, respectively). The NMDA receptor is selectively blocked by the drug APV (2-amino-5-phosphonovaleric acid). The AMPA and kainate receptors are not affected by APV but both are blocked by the drug CNQX (6-cyano-7-nitroquinoxaline-2,3dione), and thus they are sometimes called the non-*NMDA receptors.* The metabotropic glutamate receptors can be selectively activated by trans-(1S,3R)-1-amino-1, 3-cyclopentanedicarboxylic acid (ACPD). The action of ionotropic glutamate receptors is always excitatory or depolarizing, as the reversal potential of their ionic current is near zero, whereas the metabotropic receptors can produce either excitation or inhibition, depending on the reversal potential of the ionic currents that they regulate.

The NMDA receptor has several interesting properties. First, this ligand-gated channel is permeable to Ca2+ as well as to Na⁺ and K⁺ (Figure 10–4A). Second, opening the channel requires extracellular glycine as a cofactor. Under normal conditions the concentration of extracellular glycine is sufficient to allow the NMDA receptorchannel to be activated efficiently by glutamate. Third, the NMDA receptor is unique among ligand-gated channels thus far characterized because its opening depends on membrane voltage as well as transmitter. The voltage-dependence is caused by a mechanism that is quite different from that employed by the voltage-gated channels that generate the action potential. In the latter, changes in membrane potential are translated into conformational changes in the channel by an intrinsic voltage-sensor. In the NMDA receptors,

Figure 10-3 The two most common morphological types of synapses in the central nervous system are Gray type I and type II. Type I is usually excitatory, exemplified by glutamatergic synapses; type II is usually inhibitory, exemplified by GABAergic synapses. Differences include the shape of vesicles, prominence of presynaptic densities, total area of the active zone, width of the synaptic cleft, and presence of a dense basement membrane. Type I synapses typically contact specialized projections on the dendrites, called spines, and less commonly contact the shafts of dendrites. Type II synapses often contact the cell body and dendritic shaft.

however, depolarization removes an extrinsic plug from the channel. At the resting membrane potential (–65 mV) extracellular Mg²⁺ binds tightly to a site in the pore of the channel, blocking ionic current. But when the membrane is depolarized (for example, by the opening of AMPA receptor-channels), Mg²⁺ is expelled from the channel by electrostatic repulsion, allowing Na⁺ and Ca²⁺ to enter (Figure 10–5).

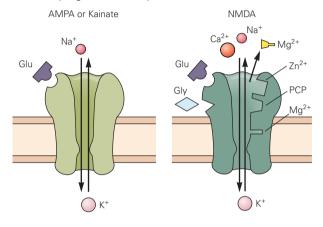

The NMDA receptor has the further interesting property that it is inhibited by the hallucinogenic drug phencyclidine (PCP, also known as angel dust) and by MK801, both of which bind to a site in the pore of the channel that is distinct from the Mg²⁺ binding site (Figure 10–4A). Indeed, blockade of NMDA receptors produces symptoms that resemble the hallucinations associated with schizophrenia, whereas certain antipsychotic drugs enhance current flow through the NMDA receptor-channels. This has led to the hypothesis that schizophrenia may involve a defect in NMDA receptor function.

At most central synapses that use glutamate as the transmitter, the postsynaptic membrane contains both NMDA and AMPA receptors. The contributions of

current through NMDA and AMPA receptors to the total excitatory postsynaptic current (EPSC) can be dissected using pharmacological antagonists in a voltageclamp experiment (Figure 10-6). At the normal resting potential of most neurons, the NMDA receptor-channels are largely inhibited by Mg²⁺. As a result, the EPSC is predominantly determined by charge flow through the AMPA receptors, which generate a current with a very rapid rising phase and very rapid decay phase. However, as a neuron becomes depolarized, Mg²⁺ is driven out of the mouth of the NMDA receptors and more charge flows through these channels. Thus, the NMDA receptor conducts current maximally when two conditions are met: Glutamate is present, and the cell is depolarized (Figure 10-6). That is, the NMDA receptor acts as a "coincidence detector," detecting a timing relationship between activation of the presynaptic and postsynaptic cells. In addition, because of the intrinsic kinetics of ligand gating, the current through the NMDA receptor rises and decays with a much slower time course than the AMPA receptor current. As a result, the NMDA receptors contribute to a late, slow phase of the EPSC and EPSP.

As most glutamatergic synapses contain AMPA receptors that are capable of triggering an action potential, what is the function of the NMDA receptor? At first glance the function of these receptors is even more puzzling because they are normally blocked by Mg²⁺ at the resting potential. However, when glutamate

A lonotropic glutamate receptor

B Metabotropic glutamate receptor

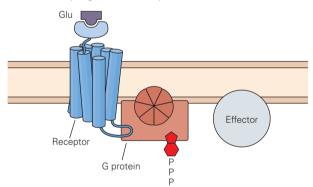

Figure 10–4 Different classes of glutamate receptors regulate excitatory synaptic actions in neurons in the spinal cord and brain.

A. Three classes of ionotropic glutamate receptors directly gate ion channels permeable to cations. The AMPA and kainate type of receptors bind the glutamate agonists AMPA or kainate, respectively. These receptors contain a channel that is permeable to Na⁺ and K⁺. The NMDA receptor, which binds the glutamate agonist NMDA, contains a channel permeable to Ca²⁺, K⁺, and Na⁺. It has binding sites for glutamate, glycine, Zn²⁺, phencyclidine (PCP, or *angel dust*), MK801 (an experimental drug), and Mg²⁺, each of which regulates the functioning of the channel differently.

B. The metabotropic glutamate receptors indirectly gate ion channels by activating a GTP-binding protein, which in turn interacts with effector molecules that alter metabolic and ion channel activity (see Chapter 11).

is paired with depolarization, the NMDA receptors uniquely conduct Ca²⁺ into the postsynaptic cell. This leads to a rise in intracellular [Ca2+] that can activate various calcium-dependent signaling cascades, including calcium-calmodulin-dependent protein kinase II (CaMKII) (see Chapter 11). Thus NMDA receptor activation can translate electrical signals into biochemical ones. Some of these biochemical reactions lead to longlasting changes in synaptic strength, a set of processes called long-term synaptic plasticity that are thought to be important during synapse development and for regulating neural circuits in the adult brain. In particular, an NMDA receptor-dependent long-term potentiation (LTP) of excitatory synaptic transmission has been implicated in certain forms of memory storage (see Chapters 66 and 67).

However, there is also a potential downside to the entry of Ca²⁺ through the NMDA receptors. Excessively high concentrations of glutamate are thought to result in an overload of Ca2+ in the postsynaptic neurons. Such high levels of Ca²⁺ can be toxic to neurons. In tissue culture even a brief exposure to high concentrations of glutamate can kill many neurons, an action called *glutamate excitotoxicity*. The high concentrations of intracellular Ca²⁺ are thought to activate calciumdependent proteases and phospholipases and lead to the production of free radicals that are toxic to the cell. Glutamate toxicity may contribute to cell damage after stroke, to the cell death that occurs with episodes of rapidly repeated seizures experienced by patients who have status epilepticus, and to degenerative diseases such as Huntington disease. Agents that selectively block the NMDA receptor may protect against the toxic effects of glutamate and have been tested clinically. Unfortunately, the hallucinations that accompany NMDA receptor blockade have so far limited the usefulness of such compounds. A further complication of attempts to control excitotoxicity by blocking NMDA receptor function is that physiological levels of NMDA receptor activation can actually protect neurons from damage and cell death.

The Excitatory Ionotropic Glutamate Receptors Are Encoded by a Distinct Gene Family

What are the molecular bases for the biophysical function of glutamate receptors and how are these receptors related to other ligand-gated ion channels? Over the past 20 years the genes coding for the subunits of all the major neurotransmitter receptors have been identified. This molecular analysis demonstrates evolutionary linkages among the structure of receptors that enable us to classify them into three distinct

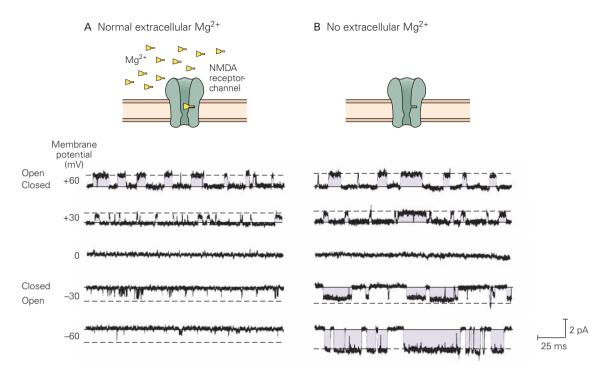

Figure 10–5 Opening of single NMDA receptor-channels depends on voltage in addition to glutamate. These recordings are from individual NMDA receptor-channels (from rat hippocampal cells in culture). Downward deflections indicate pulses of inward (negative) current; upward deflections indicate outward (positive) current. (Reproduced, with permission, from J. Jen and C. F. Stevens.)

A. When Mg²⁺ is present in normal concentration in the extracellular solution (1.2 mM), the channel is largely blocked at the resting potential (–60 mV). At negative membrane potentials

only brief, flickery, inward currents are seen upon channel opening because of the $\mathrm{Mg^{2+}}$ block. Substantial depolarization (to +30 mV or +60 mV) relieves the $\mathrm{Mg^{2+}}$ block, permitting longer-lasting pulses of outward current through the channel.

B. When Mg²⁺ is removed from the extracellular solution, the opening and closing of the channel do not depend on voltage. The channel is open at the resting potential of –60 mV, and the synaptic current reverses near 0 mV, like the total synaptic current (see Figure 10–6B).

families (Figure 10–7). One family includes the genes encoding the kainate, AMPA, and NMDA receptors; the genes encoding the AMPA and kainate receptors are more closely related to one another than are the genes encoding the NMDA receptors. Surprisingly this gene family bears little resemblance to the two other gene families that encode ionotropic receptors (one that encodes the ACh, GABA, and glycine receptors, and one that encodes ATP receptors, as described below).

Unlike the pentameric nicotinic ACh receptor family, the AMPA, kainate, and NMDA receptors are tetrameric proteins with four subunits arranged around a central pore. The AMPA receptor subunits are encoded by four separate genes (*GluA1-GluA4*), and there are five different kainate receptor subunit genes (*GluK1-GluK5*). Most of the AMPA and kainate receptors are heteromers composed of two different types of *GluA* and *GluK* subunits,

respectively. The NMDA receptors are encoded by a family consisting of five genes that fall into two groups, the single *GluN1* gene and the four *GluN2A-D* genes. Each NMDA receptor contains two GluN1 subunits and two of the different types of GluN2 subunits. In addition, many of these subunit genes are alternatively spliced, generating further diversity. Autoantibodies to the AMPA receptor GluA3 subunit are thought to play an important role in some forms of epilepsy. These antibodies actually mimic glutamate by activating

¹This nomenclature used for the glutamate receptor subunits conforms to recent naming conventions. In previous nomenclature used in the literature, the four AMPA receptor subunit genes were referred to as *GluR1-4* or *GluRA-D*, the kainate receptor subunit genes were referred to as *GluR5-6*, *KA1* and *KA1*, and the NMDA receptor subunit genes as *NR1* and *NR2A-D*.

GluA3-containing receptors, resulting in excessive excitation and seizures.

The amino acid sequence of the ionotropic glutamate receptor subunits and subsequent functional and biochemical studies provided the initial compelling evidence that the transmembrane topology of these subunits is very different from that of the nicotinic ACh receptor (Figure 10–7). Our understanding of the ionotropic glutamate receptors was then greatly expanded by Eric Gouaux and colleagues' determination of the high-resolution X-ray crystal structures of the isolated AMPA receptor ligand binding domain and of an intact AMPA receptor-channel formed by GluA2 subunits (Figure 10–8).

A Early and late components of synaptic current

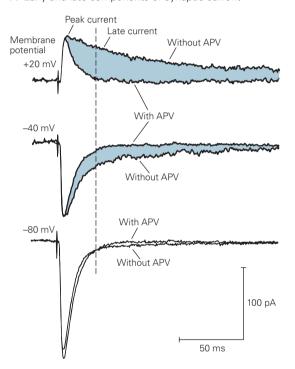

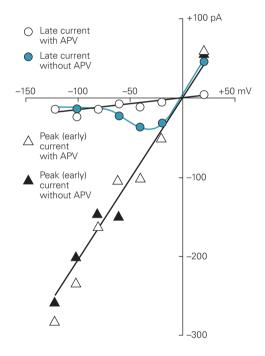

Figure 10–6 The contributions of the AMPA and NMDA glutamate receptor-channels to the excitatory postsynaptic current. These voltage-clamp current records are from a cell in the hippocampus. Similar receptor-channels are present in motor neurons and throughout the brain. (Adapted, with permission, from Hestrin et al. 1990.)

A. The drug APV selectively binds to and blocks the NMDA receptor. Shown here is the excitatory postsynaptic current (EPSC) before and during application of $50~\mu\text{M}$ APV at three different membrane potentials. The difference between the traces (blue region) represents the contribution of the NMDA receptor-channel to the EPSC. The current that remains in the presence of APV is the contribution of the AMPA receptor-channels. At -80~mV there is no current through the NMDA receptor-channels because of pronounced Mg²+ block (see Figure 10–5). At -40~mV a small late inward current through NMDA receptor-channels is evident. At +20~mV the late component is more prominent and has reversed to become an outward current. The vertical dotted line indicates the time 25 ms after the peak of the synaptic current, which is used for the calculations of late current in part B.

B Current-voltage relationship of the synaptic current

B. The postsynaptic currents through the NMDA and AMPA receptor-channels differ in their dependence on the membrane potential. The current through the AMPA receptor-channels contributes to the early phase of the synaptic current (filled triangles). The early phase is measured at the peak of the synaptic current and plotted here as a function of membrane potential. The current through the NMDA receptor-channels contributes to the late phase of the synaptic current (filled circles). The late phase is measured 25 ms after the peak of the synaptic current (dotted line in part A), a time at which the AMPA receptor component has decayed almost to zero. Note that the AMPA receptor-channels behave as simple resistors; current and voltage have a linear relationship. In contrast, current through the NMDA receptor-channels is nonlinear and increases as the membrane is depolarized from -80 to -40 mV, owing to progressive relief of Mg2+ block. The reversal potential of both receptor-channel types is at 0 mV. The components of the synaptic current in the presence of 50 µm APV are indicated by the unfilled circles and triangles. Note how APV blocks the late (NMDA receptor) component but not the early (AMPA receptor) component of the EPSC.

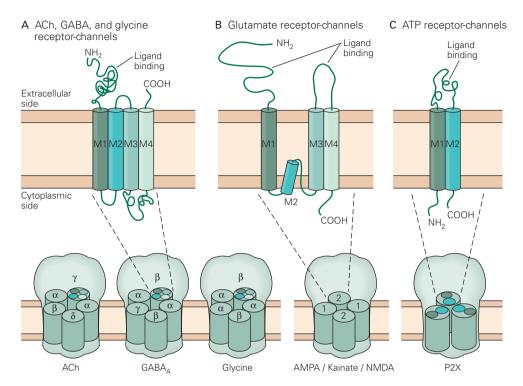

Figure 10-7 The three families of ligand-gated channels.

A. The nicotinic ACh, GABA $_{\rm A}$, and glycine receptor-channels are all pentamers composed of several types of related subunits. As shown here, the ligand-binding domain is formed by the extracellular amino-terminal region of the protein. Each subunit has a membrane domain with four membrane-spanning α -helixes (M1–M4) and a short extracellular carboxyl terminus. The M2 helix lines the channel pore.

B. The glutamate receptor-channels are tetramers, often composed of two different types of closely related subunits (here denoted 1 and 2). The subunits have a large extracellular amino terminus, a membrane domain with three membrane-

spanning α -helixes (M1, M3, and M4), a large extracellular loop connecting the M3 and M4 helixes, and an intracellular carboxyl terminus. The M2 segment forms a loop that dips into and out of the cytoplasmic side of the membrane, contributing to the selectivity filter of the channel. The glutamate binding site is formed by residues in the extracellular amino terminus and in the M3-M4 extracellular loop.

C. The ATP receptor-channels (or purinergic P2X receptors) are trimers. Each subunit possesses two membrane-spanning α -helixes (M1 and M2) and a large extracellular loop that binds ATP. The M2 helix lines the pore.

Glutamate Receptors Are Constructed from a Set of Modules

AMPA receptors are composed of three distinct modules: an extracellular amino-terminal domain, an extracellular ligand-binding domain, and a transmembrane domain (Figure 10–8A,B). The transmembrane domain contains three transmembrane α -helixes (M1, M3, and M4) and a loop (M2) between the M1 and M3 helixes that dips into and out of the cytoplasmic side of the membrane. This M2 loop is thought to form the selectivity filter of the channel. It adopts a structure similar to the pore-lining P loop of K⁺ channels, except that in K⁺ channels the P loop dips into and out of the extracellular surface of the membrane (see Figure 5–15).

Both the extracellular amino-terminal domain and the extracellular ligand binding domain are homologous to bacterial amino acid binding proteins. Each domain forms a bi-lobed clamshell-like structure similar to the structure of the bacterial proteins, in which the amino acid is bound within the clamshell. The amino-terminal domain does not bind glutamate but is homologous to the glutamate binding domain of metabotropic glutamate receptors. In the ionotropic glutamate receptors this domain is involved in subunit assembly, the modulation of receptor function by ligands other than glutamate, and the interaction with other synaptic proteins to regulate synapse development.

The ligand-binding domain is formed by two distinct regions in the linear sequence of the protein. One region is located in the extracellular amino terminus of

the protein from the end of the amino-terminal domain up to the M1 transmembrane helix; the second region is formed by the large extracellular loop connecting the M3 and M4 helixes. In the ionotropic receptors, the binding of a molecule of glutamate within the clamshell triggers the closure of the lobes of the clamshell; competitive antagonists also bind to the clamshell but fail to trigger clamshell closure. Thus the conformational change associated with clamshell closure is thought to be coupled to the opening of the ion channel.

Given the homology among the various subtypes of glutamate receptors, it is likely that the kainate and NMDA receptors adopt an overall structure similar to that of the homomeric GluA2 receptor. However, there are also likely to be some important differences that give rise to the distinct physiological functions of the different receptors. As we saw previously, the NMDA receptor-channels are permeable to Ca²⁺, whereas most AMPA receptors are not. These differences have been localized to a single amino acid residue in the pore-forming M2 loop (Figure 10–9A). All NMDA receptor subunits contain the neutral residue asparagine at this position in the pore. In most types of AMPA receptor subunits this residue is the uncharged amino acid glutamine. However,

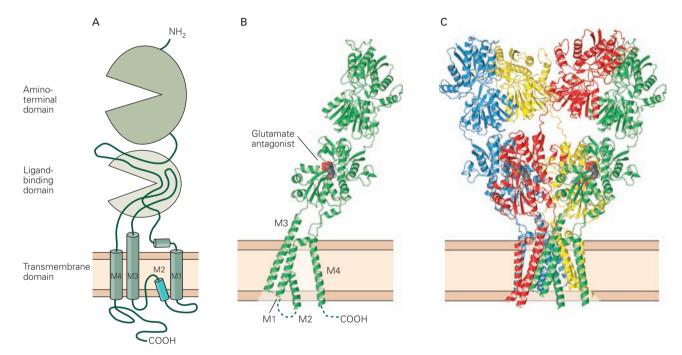

Figure 10-8 Structure of an ionotropic glutamate receptor.

A. Schematic organization of the ionotropic glutamate receptors. The receptors contain a large extracellular amino terminus, followed by a transmembrane domain containing three membrane-spanning α -helixes (M1, M3, and M4) and a loop that dips into the cytoplasmic side of the membrane (M2). The ligand-binding domain is formed by the extracellular region of the receptor on the amino-terminal side of the M1 segment and by the extracellular loop connecting M3 and M4. These two regions intertwine to form a clamshell structure that binds glutamate and various pharmacological agonists and competitive antagonists. A second clamshell structure is formed at the extreme amino terminus of the receptor. This amino-terminal domain is thought to modulate receptor function and synapse development. It does not bind glutamate in the ionotropic receptors. (Reproduced, with permission, from Armstrong et al. 1998.)

B. Three-dimensional X-ray crystal structure of an AMPA receptor composed solely of GluA2 subunits. A side view of the structure of a single GluA2 subunit showing the amino-terminal domain, ligand-binding domain, and transmembrane domain.

The M1, M3, and M4 transmembrane α -helixes are indicated, as is the short α -helix in the M2 loop. A molecule of a competitive antagonist of glutamate bound to the ligand-binding domain is shown in a space-filling representation. The cytoplasmic loops connecting the membrane α -helixes were not resolved in the structure and have been drawn as dashed lines. (Reproduced, with permission, from Sobolevsky, Rosconi and Gouaux, 2009.)

C. A side view of the structure of the tetrameric receptor. The four GluA2 subunits associate through the extracellular domains as a pair of dimers (two-fold symmetry). In the aminoterminal domain, one dimer is formed by the blue and yellow subunits, and the other dimer is formed by the red and green subunits. In the ligand-binding domain, the subunits change partners. In one dimer the blue subunit associates with the red subunit, whereas in the other dimer the yellow subunit associates with the green subunit. In the transmembrane region the subunits associate as a four-fold symmetric tetramer. This is a highly unusual subunit arrangement whose significance is not fully understood. (Reproduced, with permission, from Sobolevsky, Rosconi and Gouaux, 2009.)

Arainine

residue

Glutamine

residue

A. Comparison of amino acid sequences in the M2 region of the AMPA receptor-channel coded by unedited and edited transcripts of the *GluA2* gene. The unedited transcript codes for the polar residue glutamine (**Q**, using the single-letter amino acid notation), whereas the edited transcript codes for the positively charged residue arginine (**R**). In the adult the GluA2 protein exists almost exclusively in the edited form.

B. AMPA receptor-channels expressed from unedited transcripts conduct Ca²⁺ (left traces), whereas those expressed from edited transcripts do not (right traces). The top and bottom traces show currents elicited by glutamate with either extracellular Na⁺ (top traces) or Ca²⁺ (bottom traces) as the predominant permeant cation. (Reproduced, with permission, from Sakmann 1992.)

in the GluA2 subunit the corresponding M2 residue is arginine, a positively charged basic amino acid. Inclusion of even a single GluA2 subunit causes the AMPA receptor-channels to have a very low permeability to Ca²⁺, most likely as a result of strong electrostatic repulsion by the arginine. Some cells form AMPA receptors that lack the GluA2 subunit. Such AMPA receptor-channels generate a significant Ca²⁺ influx, because their pores lack the positively charged arginine residue.

Peter Seeburg and his colleagues made the remarkable discovery that the DNA of the GluA2 gene does not actually encode an arginine residue at this position in the M2 loop but rather codes for a glutamine residue. After transcription the codon for glutamine in the *GluA*2 mRNA is replaced with one for arginine because of a chemical modification of a single nucleotide base through an enzymatic process termed RNA editing (Figure 10–9A). The importance of this RNA editing is underscored by a genetically engineered mouse that Seeburg and colleagues designed to express a GluA2 gene in which the glutamine residue could no longer be edited to an arginine. Such mice develope seizures and die within a few weeks after birth, presumably caused by excess intracellular Ca2+ as all the AMPA receptors in these mice have a high Ca²⁺ permeability.

NMDA and AMPA Receptors Are Organized by a Network of Proteins at the Postsynaptic Density

How are the different glutamate receptors localized and arranged at excitatory synapses? Like most ionotropic receptors, glutamate receptors are normally clustered at postsynaptic sites in the membrane, opposed to glutamatergic presynaptic terminals. The vast majority of excitatory synapses in the mature nervous system contain both NMDA and AMPA, whereas in early development synapses containing only NMDA receptors are common. How are synaptic receptors clustered and targeted to appropriate sites? We are now beginning to appreciate that a large number of regulatory proteins that constitute the postsynaptic density help organize the three-dimensional structure of the postsynaptic cell membrane, including the localization of postsynaptic receptors (Figure 10–10).

The postsynaptic density is a remarkably stable structure, permitting its biochemical isolation, purification and characterization. Electron microscopic studies of intact and isolated postsynaptic densities provide a strikingly detailed view of their structure. By using gold-labeled antibodies it is possible to identify specific protein components of the postsynaptic membrane, including the location and number of glutamate receptors. A typical PSD of around 350 nm in diameter contains about

A. Electron microscope images of biochemically purified post-synaptic densities, showing organization of protein network. The membrane lipid bilayer is no longer present. Left: View of postsynaptic density from what would normally be the outside of the cell. This image consists of the extracellular domains of various receptors and membrane proteins. Right: View of a postsynaptic density from what would normally be the cytoplasmic side of the membrane. White dots show immunolabeled guanylate kinase anchoring protein, an important component of the PSD.

B. Schematic view of localization and typical number of NMDA receptors, AMPA receptors, and PSD-95, a prominent postsynaptic density protein, at a synapse.

C. Schematic view of the network of receptors and their interacting proteins in the postsynaptic density. PSD-95 contains three PDZ domains at its amino terminus and two other protein interacting motifs at its carboxyl terminus, an SH3 domain and guanylate kinase (GK) domain. Certain PDZ domains of PSD-95 bind to the carboxyl terminus of the GluN2 subunit of the NMDA receptor. PSD-95 does not directly interact with AMPA receptors but binds to the carboxyl terminus of the TARP family of membrane proteins, which interact with the AMPA receptors as auxiliary subunits. PSD-95 also acts as a scaffold for various cytoplasmic proteins by binding to the guanylate-kinase-associated protein (GKAP), which interacts with Shank, a large protein that associates into a meshwork linking the various components of the postsynaptic density. PSD-95 also interacts with the cytoplasmic region of neuroligin. The metabotropic glutamate receptor is localized on the periphery of the synapse. It interacts with the protein Homer, which in turn binds to Shank.

20 NMDA receptors, which tend to be localized near the center of the PSD, and 10 to 50 AMPA receptors, which are less centrally localized. The metabotropic glutamate receptors are located on the periphery, outside the main area of the PSD. All three receptor types interact with a wide array of cytoplasmic and membrane proteins to ensure their proper localization.

One of the most prominent proteins in the postsynaptic density important for the clustering of glutamate receptors is PSD-95 (postsynaptic density protein of 95 kD molecular weight). PSD-95 is a membraneassociated protein that contains three repeated regions—the so-called PDZ domains—important for protein-protein interactions. The PDZ domains bind to specific sequences at the extreme carboxy terminus of a number of cellular proteins. They are named PDZ after the three proteins in which they were first identified: PSD-95, the DLG tumor suppressor protein in Drosophila, and a protein termed ZO-1. The PDZ domains of PSD-95 bind the NMDA receptor and the Shakertype voltage-gated K⁺ channel, thereby localizing and concentrating these channels at postsynaptic sites. PSD-95 also interacts with the postsynaptic membrane protein neuroligin, which forms an extracellular contact in the synaptic cleft with the presynaptic membrane protein neurexin, an interaction important for synapse development. Mutations in neuroligin are thought to contribute to some cases of autism.

Although PSD-95 does not directly bind to AMPA receptors, it does interact with an auxiliary subunit of these receptors termed the transmembrane AMPA receptor regulatory protein (TARP). The TARP proteins contain four transmembrane segments with a cytoplasmic C-terminus. These proteins strongly regulate the trafficking, synaptic localization, and gating of the AMPA receptors. The first TARP family member to be identified was stargazin, which was isolated through a genetic screen in the stargazer mutant mouse, so named because these animals have a tendency to tip their heads backward and stare upward. Loss of stargazin leads to a complete loss of AMPA receptors from cerebellar granule cells, which results in cerebellar ataxia and frequent seizures. Other members of the TARP family are similarly required for AMPA receptor trafficking to the surface membrane of other types of neurons.

The proper localization of AMPA receptors by stargazin depends on the interaction between its C-terminus and PSD-95. AMPA receptors also bind to a distinct PDZ domain protein called GRIP, and metabotropic glutamate receptors interact with yet another PDZ domain protein called Homer. In addition to interacting with receptors, proteins with PDZ domains interact with many other cellular proteins, including proteins that bind to the actin cytoskeleton, providing a scaffold

around which a complex of postsynaptic proteins is constructed. Indeed, a biochemical analysis of the post-synaptic density has identified dozens of proteins that participate in NMDA or AMPA receptor complexes.

Inhibitory Synaptic Action Is Usually Mediated by Ionotropic GABA and Glycine Receptor-Channels That Are Permeable to Chloride

Although glutamatergic excitatory synapses account for the vast majority of synapses in the brain, inhibitory synapses play an essential role in the nervous system both by preventing too much excitation and by helping coordinate activity among networks of neurons. Inhibitory postsynaptic potentials in spinal motor neurons and most central neurons are generated by the amino acid neurotransmitters GABA and glycine. GABA is a major inhibitory transmitter in the brain and spinal cord. It acts on two receptors, GABA_A and GABA_B. The GABA_A receptor is an ionotropic receptor that directly opens a Cl⁻ channel. The GABA_B receptor is a metabotropic receptor that activates a second-messenger cascade, which often indirectly activates a K+ channel (see Chapter 11). Glycine, a less common inhibitory transmitter in the brain, also activates ionotropic receptors that directly open Cl⁻ channels. Glycine is the major transmitter released in the spinal cord by the interneurons that inhibit antagonist muscles.

Eccles and his colleagues determined the ionic mechanism of the IPSP in spinal motor neurons by systematically changing the level of the resting membrane potential in a motor neuron and stimulating a presynaptic inhibitory interneuron (Figure 10-11). When the motor neuron membrane is held at the normal resting potential (-65 mV), a small hyperpolarizing potential is generated when the interneuron is stimulated. When the motor neuron membrane is held at -70 mV, no change in potential is recorded when the interneuron is stimulated. But at potentials more negative than –70 mV the motor neuron generates a depolarizing response following stimulation of the inhibitory interneuron. This reversal potential of -70 mV corresponds to the Cl⁻ equilibrium potential in spinal motor neurons (the extracellular concentration of Cl⁻ is much greater than the intracellular concentration). Thus, at -70 mV the tendency of Cl to diffuse into the cell down its chemical concentration gradient is balanced by the electrical force (the negative membrane potential) that opposes Cl⁻ influx. Replacement of extracellular Cl- with an impermeant anion reduces the size of the IPSP and shifts the reversal potential to more positive values in accord with the predictions of the Nernst equation. Thus, the IPSP results from an increase in Cl⁻ conductance.

A Experimental setup C Reversal of inhibitory synaptic potential Presynaptic Current Current Recording Recording passing passing Postsynaptic Postsynaptic CIflux potential current $V_{\rm m}$ Inhibitory Motor interneuron -40 mVneuron B Reduction of excitatory synaptic potential by inhibition 1 EPSP alone 2 IPSP alone 3 EPSP + IPSP +40 mV Action potential $\begin{array}{c} E_{\rm CI} \\ (E_{\rm IPSP}) \end{array}$ -70 mV - E_{EPSP} 0 mV Eĸ -80 mV -55 mV Threshold -65 mV -70 mV -100 mV EPSP alone IPSP alone IPSP + EPSP

Figure 10–11 Inhibitory actions at chemical synapses result from the opening of ion channels selective for Cl⁻.

A. In this hypothetical experiment two electrodes are placed in the presynaptic interneuron and two in the postsynaptic motor neuron. The current-passing electrode in the presynaptic cell is used to produce an action potential; in the postsynaptic cell it is used to alter the membrane potential systematically prior to the presynaptic input.

B. Inhibitory actions counteract excitatory actions. **1.** A large EPSP occurring alone depolarizes the membrane toward E_{EPSP} and exceeds the threshold for generating an action potential. **2.** An IPSP alone moves the membrane potential away from the threshold toward E_{CI} , the Nernst potential for CI⁻ (–70 mV). **3.** When inhibitory and excitatory synaptic potentials occur together, the effectiveness of the EPSP is reduced, preventing it from reaching the threshold for an action potential.

C. The IPSP and inhibitory synaptic current reverse at the equilibrium potential for Cl⁻. 1. A presynaptic spike produces a hyperpolarizing IPSP at the resting membrane potential (-65 mV). The IPSP is larger when the membrane potential is set at -40 mV due to the increased driving force on Cl⁻. When the membrane potential is set at -70 mV the IPSP is nullified. This reversal potential for the IPSP occurs at E_{CI} . With further hyperpolarization of the membrane the IPSP is inverted to a depolarizing postsynaptic potential (at -80 and -100 mV) because the membrane potential is negative to $E_{\rm Cl}$. 2. The reversal potential of the inhibitory postsynaptic current measured under voltage clamp. An inward (negative) current flows at membrane potentials negative to the reversal potential (corresponding to an efflux of Cl⁻) and an outward (positive) current flows at membrane potentials positive to the reversal potential (corresponding to an influx of Cl⁻). (Up arrows = efflux, down arrows = influx.)

Currents Through Single GABA and Glycine Receptor-Channels Can Be Recorded

The currents through single GABA and glycine receptor-channels, the unitary currents, have been measured using the patch-clamp technique. Both transmitters activate Cl⁻ channels that open in an all-or-none manner, similar to the opening of ACh and

glutamate-gated channels. The conductance of a glycine receptor-channel (46 pS) is larger than that of a GABA_A receptor-channel (30 pS). As a result, the unitary current through glycine-gated channels is somewhat larger than that of GABA_A receptor-channels (Figure 10–12). This difference results because the diameter of the glycine receptor-channel pore is slightly larger than that of the GABA_A receptor-channel pore.

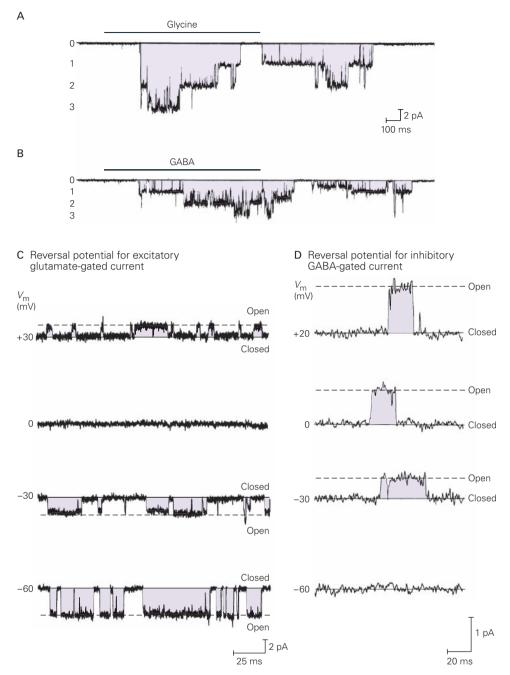

Figure 10–12 Comparison of single-channel excitatory currents activated by glutamate and inhibitory currents activated by GABA and glycine.

- A. Single-channel currents through three glycine receptorchannels in a patch from a mouse spinal neuron. (Reproduced, with permission, from Bormann et al. 2007.)
- **B.** Single-channel currents through GABA receptor-channels in the same patch. In A and B the membrane was held at a voltage negative to the Cl⁻ equilibrium potential, so channel openings generate an inward current owing to an efflux of Cl⁻. (Reproduced, with permission, from Bormann et al. 2007.)
- C. Excitatory current through a single NMDA receptor-channel in a rat hippocampal neuron. As the membrane potential is moved in a depolarizing direction (from –60 to –30 mV), the current pulses become smaller. At 0 mV (the reversal potential

for the EPSP) the current pulses are nullified, and at +30 mV they invert and are outward. The reversal potential at 0 mV is the weighted average of equilibrium potentials for Na $^+$, Ca $^{2+}$, and K $^+$, the three ions responsible for generating this current. Note: In this recording there was no Mg $^{2+}$ in the external solution so the NMDA receptor-channel openings are voltage-independent. (Reproduced, with permission, from J. Jen and C. F. Stevens.)

D. Inhibitory current through a single GABA-activated channel in a rat hippocampal neuron. The current is nullified at approximately –60 mV (the reversal potential for the IPSP in this cell). At more depolarized levels the current pulses are outward (corresponding to the influx of Cl⁻). This reversal potential lies near the equilibrium potential for Cl⁻, the only ion contributing to this current. (Reproduced, with permission, from B. Sakmann.)

The inhibitory action of these Cl $^-$ channels can be demonstrated by comparing the reversal potentials of current through a GABA $_{\rm A}$ receptor-channel and a glutamate receptor-channel. The excitatory current reverses at 0 mV (Figure 10–12C). Therefore, opening of glutamate receptor-channels at the normal resting potential generates an inward current (influx of positive charge), driving the membrane past threshold. In contrast, the inhibitory current becomes nullified and begins to reverse at values more negative than $-60~{\rm mV}$ (Figure 10–12D). Thus, the opening of GABA $_{\rm A}$ receptor-channels at typical resting potentials normally generates an outward current (influx of negative charge), preventing the membrane from reaching threshold.

Chloride Currents Through Inhibitory GABA_A and Glycine Receptor-Channels Normally Inhibit the Postsynaptic Cell

In a typical neuron the resting potential of -65 mV is slightly more positive than $E_{\rm Cl}$ (-70 mV). At this resting potential the chemical force driving Cl⁻ into the cell is slightly greater than the electrical force opposing Cl⁻ influx—that is, the electrochemical driving force on Cl⁻ ($V_{\rm m}-E_{\rm Cl}$) is positive. As a result, the opening of Cl⁻ channels leads to a positive current, based on the relation $I_{\rm Cl}=g_{\rm Cl}(V_{\rm m}-E_{\rm Cl})$. Because the charge carrier is the negatively charged Cl⁻ ion, the positive current corresponds to an influx of Cl⁻ into the neuron, down its electrochemical gradient. This causes a net increase in the negative charge on the inside of the membrane—the membrane becomes hyperpolarized.

Some central neurons have a resting potential that is approximately equal to E_{Cl} . In such cells an increase in Cl⁻ conductance does not change the membrane potential—the cell does not become hyperpolarized because the electrochemical driving force on Cl⁻ is nearly zero. However, the opening of Cl⁻ channels in such a cell still inhibits the cell from firing an action potential in response to a near-simultaneous EPSP. This is because the depolarization produced by an excitatory input depends on a weighted average of the batteries for all types of open channels—that is, the batteries for the excitatory and inhibitory synaptic conductances and the resting conductances—with the weighting factor equal to the total conductance for a particular type of channel (see Chapter 9, Postscript). Because the battery for Cl⁻ channels lies near the resting potential, opening these channels helps hold the membrane near its resting potential during the EPSP by increasing the weighting factor for the Cl⁻ battery.

The effect that the opening of Cl⁻ channels has on the magnitude of an EPSP can also be described in terms of Ohm's law. Accordingly, the amplitude of the depolarization during an EPSP, ΔV_{EPSP} , is given by:

$$\Delta V_{\text{EPSP}} = I_{\text{EPSP}}/g_1$$

where $I_{\rm EPSP}$ is the excitatory synaptic current and g_1 is the total conductance of all other channels open in the membrane, including resting channels and any contributions from the transmitter-gated Cl-channels. Because the opening of the Cl-channels increases the resting conductance, the depolarization during the EPSP decreases. This consequence of synaptic inhibition is called the *short-circuiting* or *shunting* effect.

The different biophysical properties of synaptic conductances can be also understood as distinct mathematical operations carried out by the postsynaptic neuron. Thus, inhibitory inputs that hyperpolarize the cell perform a *subtraction* on the excitatory inputs, whereas those that shunt the excitation perform a *division*. Adding excitatory inputs (or removing nonshunting inhibitory inputs) results in a *summation*. Finally, the combination of an excitatory input with the removal of an inhibitory shunt produces a *multiplication*.

In some cells, such as those with metabotropic $GABA_B$ receptors, inhibition is caused by the opening of K^+ channels. Because the K^+ equilibrium potential of neurons ($E_K = -80$ mV) is always negative to the resting potential, opening K^+ channels inhibits the cell even more profoundly than opening Cl^- channels (assuming a similar-size synaptic conductance). $GABA_B$ responses turn on more slowly and persist for a longer time compared with $GABA_A$ responses.

Paradoxically, under some conditions the activation of GABA_A receptors in brain cells can cause excitation. This is because the influx of Cl⁻ after intense periods of stimulation can be so great that the intracellular Cl⁻ concentration increases substantially. It may even double. As a result, the Cl⁻ equilibrium potential may become more positive than the resting potential. Under these conditions the opening of Cl channels leads to Cl⁻ efflux and depolarization of the neuron. Such depolarizing Cl⁻ responses occur normally in some neurons in newborn animals, where the intracellular Cl⁻ concentration tends to be high even at rest. This is because the K⁺-Cl⁻ cotransporter is expressed at low levels during early development, as discussed in Chapter 6. Depolarizing Cl⁻ responses may also occur in the distal dendrites of more mature neurons and perhaps also at their axon initial segment. Such excitatory GABAA receptor actions in adults may contribute to epileptic discharges in which large, synchronized, and depolarizing GABA responses are observed.

Ionotropic Glutamate, GABA, and Glycine Receptors Are Transmembrane Proteins Encoded by Two Distinct Gene Families

The genes coding for the GABA_A and glycine receptors are closely related to each other. More surprisingly, the GABA_A and glycine receptors are structurally related to the nicotinic ACh receptors, even though the latter select for cations. Thus, these receptors are members of one large gene family (Figure 10–7A). In contrast, the glutamate receptors have evolved from a different class of proteins and thus represent a second gene family of ligand-gated channels (Figure 10–7B).

Ionotropic GABA_A and Glycine Receptors Are Homologous to Nicotinic ACh Receptors

Like nicotinic ACh receptor-channels, the GABA_A and glycine receptor-channels are each composed of five subunits that are encoded by related gene families (Figure 10–7A). The GABA_A receptors are usually composed of two α -, two β -, and one γ - or δ -subunit. The receptors are activated by the binding of two molecules of GABA in clefts formed between the two α - and β -subunits. The glycine receptors are composed of three α - and two β -subunits and require the binding of up to three molecules of ligand to open. The transmembrane topology of each GABA_A and glycine receptor subunit is similar to that of a nicotinic ACh receptor subunit, consisting of a large extracellular ligand-binding domain followed by four hydrophobic transmembrane α-helices (labeled M1, M2, M3, and M4), with the M2 helix forming the lining of the channel pore. However, the amino acids flanking the M2 domain are strikingly different from those of the nicotinic ACh receptor. As discussed in Chapter 9, the pore of the ACh receptor contains rings of negatively charged acidic residues that help the channel select for cations over anions. In contrast, the GABA and glycine receptor-channels contain either neutral or positively charged basic residues at the homologous positions, which contributes to the selectivity of these channels for anions.

Most of the classes of receptor subunits are encoded by multiple related genes. Thus, there are six subtypes of GABA_A α -subunits (α 1- α 6), three β -subunits (β 1- β 3), three γ -subunits (γ 1- γ 3) and one δ -subunit. The genes for these different subtypes are often differentially expressed in different types of neurons, endowing their inhibitory synapses with distinct properties. The possible combinatorial arrangements of these subunits in a fully assembled pentameric receptor provides an enormous potential diversity of receptor subtypes.

The GABA_A and glycine receptors play important roles in disease and in the actions of drugs. GABAA receptors are the target for several types of drugs that are clinically important and socially abused, including general anesthetics, benzodiazepines, barbiturates, and alcohol. General anesthetics can be either gases or injectable compounds that induce a loss of consciousness and are therefore widely used during surgery. Benzodiazepines are antianxiety agents and muscle relaxants that include diazepam (Valium), lorazepam (Ativan), and clonazepam (Klonopin). Zolpidem (Ambien) is a non-benzodiazepine compound that promotes sleep. The barbiturates comprise a distinct group of hypnotics that includes phenobarbital and secobarbital. The different classes of compounds—GABA, general anesthetics, benzodiazepines, barbiturates, and alcoholbind to different sites on the receptor but act similarly to increase the opening of the GABA receptor-channel. For example, whereas GABA binds to a cleft between the α - and β -subunits, benzodiazepines bind to a cleft between the α - and γ -subunits. In addition, the binding of any one of these classes of drug influences the binding of the others. For example, a benzodiazepine (or a barbiturate) binds more strongly to the receptorchannel when GABA also is bound, and this tight binding helps stabilize the channel in the open state. In this manner, the various compounds all enhance inhibitory synaptic transmission.

How do these various compounds that all act on $GABA_A$ receptors to promote channel opening produce such diverse behavioral and psychological effects, for example, reducing anxiety versus promoting sleep? It turns out that many of these compounds interact selectively with specific subunit subtypes, which can be localized to different regions of the brain. For example, zolpidem binds selectively to $GABA_A$ receptors containing the $\alpha 1$ -subtype of subunit. In contrast, the anxiolytic effect of benzodiazepines requires binding to the $\alpha 2$ -and γ -subunits.

In addition to being important pharmacological targets, the GABA_A and glycine receptors are targets of disease and poisons. Missense mutations in the α subunit of the glycine receptor underlie an inherited neurological disorder called *familial startle disease* (or *hyperekplexia*), characterized by abnormally high muscle tone and exaggerated responses to noise. These mutations decrease the opening of the glycine receptor and so reduce the normal levels of inhibitory transmission in the spinal cord. The poison strychnine, a plant alkaloid compound, causes convulsions by blocking the glycine receptor and decreasing inhibition. Nonsense mutations that result in truncations of GABA_A receptor α - and γ -subunits have been implicated in congenital forms of epilepsy.

Some Synaptic Actions Depend on Other Types of Ionotropic Receptors in the Central Nervous System

Certain fast excitatory synaptic actions are mediated by the neurotransmitter serotonin (5-HT) acting at the 5-HT $_3$ class of ionotropic receptor-channels. These ionotropic receptors have four transmembrane segments and are structurally similar to the nicotinic ACh receptors. Like the ACh receptor-channels, 5-HT $_3$ receptor-channels are permeable to monovalent cations and have a reversal potential near 0 mV.

Finally, ionotropic receptors for adenosine triphosphate (ATP), which serves as an excitatory transmitter at selected synapses, constitute a third major family of transmitter-gated ion channels. These so-called purinergic receptors (named for the purine ring in adenosine) occur on smooth muscle cells innervated by sympathetic neurons of the autonomic ganglia as well as on certain central and peripheral neurons. At these synapses ATP activates an ion channel that is permeable to both monovalent cations and Ca²⁺, with a reversal potential near 0 mV. Several genes coding for this family of ionotropic ATP receptors (termed the P2X receptors) have been identified. The amino acid sequence and subunit structure of these ATP receptors is different from the other two ligand-gated channel families. An X-ray crystal structure of the P2X receptor reveals that it has an exceedingly simple organization in which three subunits, each containing only two transmembrane segments, surround a central pore (Figure 10–7C).

Excitatory and Inhibitory Synaptic Actions Are Integrated by the Cell into a Single Output

Up to now we have mostly focused on the physiological and molecular properties of excitatory or inhibitory synapses in isolation. However, each neuron in the central nervous system is constantly bombarded by an array of synaptic inputs from many other neurons. A single motor neuron, for example, may be innervated by as many as 10,000 different presynaptic endings. Some are excitatory, others inhibitory; some are strong, others weak. Some inputs contact the motor cell on the tips of its apical dendrites, others on proximal dendrites, some on the dendritic shaft, others on the soma. The different inputs can reinforce or cancel one another. How does a given neuron integrate these signals into a coherent output?

As we saw earlier, the synaptic potentials produced by a single presynaptic neuron typically are not large enough to depolarize a postsynaptic cell to the threshold for an action potential. The EPSPs produced in a motor neuron by most stretch-sensitive afferent neurons are only 0.2 to 0.4 mV in amplitude. If the EPSPs generated in a single motor neuron were to sum linearly, at least 25 afferent neurons would have to fire together and release transmitter to depolarize the trigger zone by the 10 mV required to reach threshold. But at the same time the postsynaptic cell is receiving excitatory inputs, it may also be receiving inhibitory inputs that prevent the firing of action potentials by either a subtractive or shunting effect. The net effect of the inputs at any individual excitatory or inhibitory synapse will therefore depend on several factors: the location, size, and shape of the synapse, the proximity and relative strength of other synergistic or antagonistic synapses, and the resting potential of the cell.

Inputs are coordinated in the postsynaptic neuron by a process called *neuronal integration*. This cellular process reflects the task that confronts the nervous system as a whole: decision making. A cell at any given moment has two options: to fire or not to fire an action potential. Charles Sherrington described the brain's ability to choose between competing alternatives as the *integrative action of the nervous system*. He regarded this decision making as the brain's most fundamental operation.

Synaptic Inputs Are Integrated to Fire an Action Potential at the Axon Initial Segment

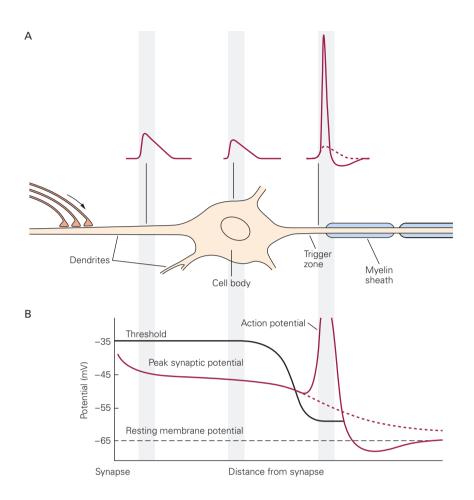

In most neurons the decision to initiate an action potential is made at one site: the initial segment of the axon (see Chapter 2). Here the cell membrane has a lower threshold for action potential generation than at the cell body or dendrites because it has a higher density of voltage-dependent Na⁺ channels (Figure 10–13). With each increment of membrane depolarization, more Na⁺ channels open, thus generating a higher density of inward current (per unit area of membrane) at the axon initial segment than elsewhere in the cell. At the initial segment the depolarization increment required to reach the threshold for an action potential (-55 mV) is only 10 mV from the resting level of -65 mV. In contrast, the membrane of the cell body must be depolarized by 30 mV before reaching its threshold (-35 mV). Therefore, synaptic excitation first discharges the region of membrane at the initial segment, also called the trigger zone. The action potential generated at this site then depolarizes the membrane of the cell body to threshold and at the same time is propagated along the axon.

Because neuronal integration involves the summation of synaptic potentials that spread to the trigger zone, it is critically affected by two passive membrane properties of the neuron (see Chapter 6). First, the

Figure 10–13 A synaptic potential arising in a dendrite can generate an action potential at the axon initial segment. (Adapted, with permission, from Eckert et al. 1988.)

A. An excitatory synaptic potential originating in the dendrites decreases with distance as it propagates passively to the soma. Nevertheless, an action potential can be initiated at the trigger zone (the axon initial segment) because the density of the Na⁺ channels in this region is high, and thus the threshold is low.

B. Comparison of the threshold for initiation of the action potential at different sites in the neuron (corresponding to drawing A). An action potential is generated when the amplitude of the synaptic potential exceeds the threshold. The dashed line shows the decay of the synaptic potential if no action potential is generated at the axon initial segment.

membrane time constant helps determine the time course of the synaptic potential and thereby controls *temporal summation*, the process by which consecutive synaptic potentials at the same site are added together in the postsynaptic cell. Neurons with a large membrane time constant have a greater capacity for temporal summation than do neurons with a shorter time constant (Figure 10–14A). As a result, the longer the time constant, the greater the likelihood that two consecutive inputs from an excitatory presynaptic neuron will summate to bring the cell membrane to its threshold for an action potential.

Second, the *length* constant of the cell determines the degree to which a local depolarization decreases as it spreads passively from a synapse along the length of the dendrite. In cells with a longer length constant, signals spread to the trigger zone with minimal decrement; in cells with a short length constant, the signals decay rapidly with distance. Because the depolarization produced at one synapse is almost never sufficient to

trigger an action potential at the trigger zone, the inputs from many presynaptic neurons acting at different sites on the postsynaptic neuron must be added together. This process is called *spatial summation*. Neurons with a large length constant are more likely to be brought to threshold by inputs arising from different sites than are neurons with a short length constant (Figure 10–14B).

Dendrites Are Electrically Excitable Structures That Can Fire Action Potentials

Propagation of signals in dendrites was originally thought to be purely passive. However, intracellular recordings from the cell body of neurons in the 1950s and from dendrites beginning in the 1970s demonstrated that dendrites could produce action potentials. Indeed, we now know that the dendrites of most neurons contain voltage-gated Na⁺, K⁺, and Ca²⁺ channels in addition to ligand-gated channels and leakage channels. In fact, the rich diversity of dendritic

conductances suggests that central neurons rely on a sophisticated repertory of electrophysiological properties to integrate synaptic inputs.

One function of the voltage-gated Na⁺ and Ca²⁺ channels in dendrites may be to amplify the EPSP. In some neurons there are sufficient concentrations of voltage-gated channels in the dendrites to serve as a local trigger zone. This can further amplify weak excitatory input that arrives at remote parts of the dendrite. When a cell has several dendritic trigger zones, each one sums the local excitation and inhibition produced by nearby synaptic inputs; if the net input is above threshold, a dendritic action potential may be generated, usually by voltage-dependent Na⁺ or Ca²⁺ channels (Figure 10–15). Nevertheless, the number of voltage-gated Na⁺ or Ca²⁺ channels in the dendrites is usually not sufficient to support the all-or-none regenerative propagation of these action potentials to the cell body. Rather, action

potentials generated in the dendrites are local events that propagate electrotonically to the cell body and axon initial segment, where they are integrated with all other input signals in the cell.

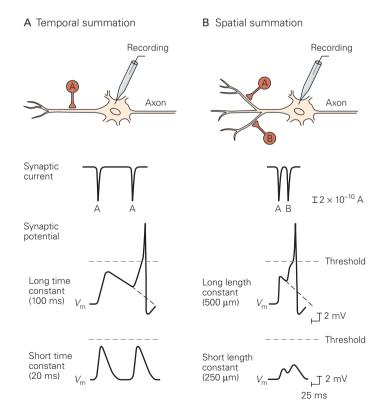

Do active conductances influence dendritic integration? There is currently a vigorous debate as to what arithmetic rules dendrites use to summate inputs. While some results indicate that dendrites are highly nonlinear devices that work by firing local spikes in individual dendritic branches, others argue that dendrites behave essentially as linear integrators (ie, they sum inputs arithmetically). In this linear scenario, dendritic conductances would balance each other to achieve a stable integration regime.

The dendritic voltage-gated channels also permit action potentials generated at the axon initial segment to propagate backward into the dendritic tree. These back-propagating action potentials are found in most

Figure 10–14 Central neurons are able to integrate a variety of synaptic inputs through temporal and spatial summation of synaptic potentials.

A. The time constant of a postsynaptic cell (see Figure 6–15) affects the amplitude of the depolarization caused by consecutive EPSPs produced by a single presynaptic neuron (A). Here the synaptic current generated by the presynaptic neuron is nearly the same for both EPSPs. In a cell with a *long* time constant the first EPSP does not fully decay by the time the second EPSP is triggered. Therefore, the depolarizing effects of both potentials are additive, bringing the membrane potential above the threshold and triggering an action potential. In a cell with a *short* time constant the first EPSP decays to the resting potential before the second EPSP is triggered. The second EPSP alone does not cause enough depolarization to trigger an action potential.

B. The length constant of a postsynaptic cell (see Figure 6-16) affects the amplitudes of two excitatory postsynaptic potentials produced by two presynaptic neurons (A and B). For illustrative purposes, both synapses are the same (500 µm) distance from the postsynaptic cell's trigger zone at the axon initial segment, and the current produced by each synaptic contact is the same. If the distance between the site of synaptic input and the trigger zone in the postsynaptic cell is only one length constant (that is, the postsynaptic cell has a length constant of 500 μ m), the synaptic potentials produced by each of the two presynaptic neurons will decrease to 37% of their original amplitude by the time they reach the trigger zone. Summation of the two potentials results in enough depolarization to exceed threshold, triggering an action potential. If the distance between the synapse and the trigger zone is equal to two length constants (ie, the postsynaptic cell has a length constant of 250 µm), each synaptic potential will be less than 15% of its initial amplitude, and summation will not be sufficient to trigger an action potential.

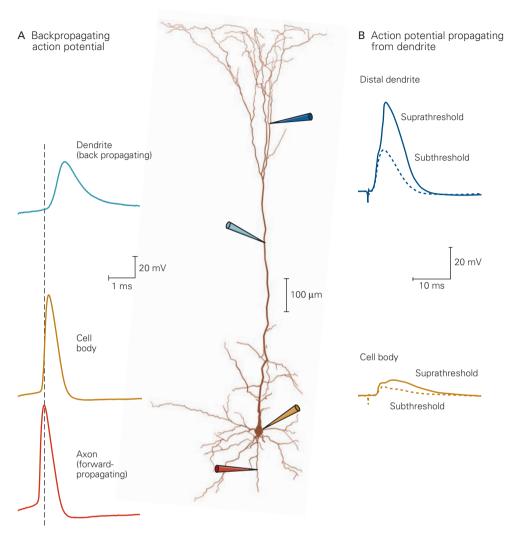

Figure 10–15 Dendrites support propagation of action potentials to and from the axon initial segment. The figure illustrates an experiment in which several electrodes are used to record membrane voltage and pass stimulating currents in the axon, the soma, and at several locations along the dendritic tree. The recording electrode and corresponding voltage trace are matched according to color. (Adapted, with permission, from Stuart et al. 2000.)

A. An action potential can be propagated from the axon initial segment to the dendrites. Such backpropagation depends on activation of voltage-gated Na⁺ channels in the dendrites. Unlike the action potential that is continually regenerated along

an axon, the amplitude of a backpropagating action potential decreases as it travels along a dendrite due to the relatively low density of voltage-gated Na⁺ channels in dendrites.

B. A strong depolarizing EPSP at a dendrite can generate an action potential that travels to the cell body. Such forward-propagating action potentials are often generated by dendritic voltage-gated Ca²⁺ channels and have a high threshold. They propagate relatively slowly and decrement with distance, often failing to reach the cell body. The **solid line** shows a suprathreshold response generated in the dendrite, and the **dotted line** shows a subthreshold response.

neurons and are largely generated by dendritic voltage-gated Na^+ channels. Although the precise role of back-propagating action potentials is unclear, they may provide a temporally precise mechanism for regulating current through the NMDA receptor by providing the depolarization necessary to remove the Mg^{2+} block (see Figure 10–5).

Synapses on a Central Neuron Are Grouped According to Physiological Function

All four regions of the nerve cell—axon, terminals, cell body, and dendrites—can in principle be presynaptic or postsynaptic sites. The most common types of contact, illustrated in Figure 10–16, are axodendritic,

axosomatic, and axo-axonic (by convention, the presynaptic element is identified first). Axodendritic synapses can occur on the dendritic shaft or on spines. Dendrodendritic and somasomatic contacts are also found, but they are rare.

The proximity of a synapse to the trigger zone is traditionally thought to be important to its effectiveness. A postsynaptic current generated at an axosomatic site should produce a greater change in membrane potential at the trigger zone, and therefore a greater influence on action potential output, than does an equal current at more remote axodendritic contacts, because of the passive cable properties of a dendrite (Figure 10–17). Nevertheless, it seems that some neurons compensate for this effect by placing more glutamate receptors at distal synapses than at proximal synapses, ensuring that inputs along the dendritic tree have a more equivalent strength at the initial segment, thereby minimizing spatial effects in dendritic integration.

In contrast to axodendritic and axosomatic input, most axo-axonic synapses have no direct effect on the trigger zone of the postsynaptic cell. Instead, they affect the activity of the postsynaptic neuron by controlling

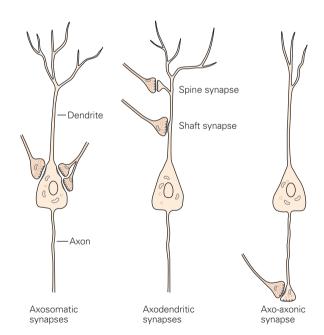

Figure 10–16 Synaptic contact can occur on the cell body, the dendrites, or the axon of the postsynaptic cell. The names of various kinds of synapses—axosomatic, axodendritic, and axo-axonic—identify the contacting regions of both the presynaptic and postsynaptic neurons (the presynaptic element is identified first). Axodendritic synapses can occur on either the shaft of a dendrite or on a specialized input zone, the spine.

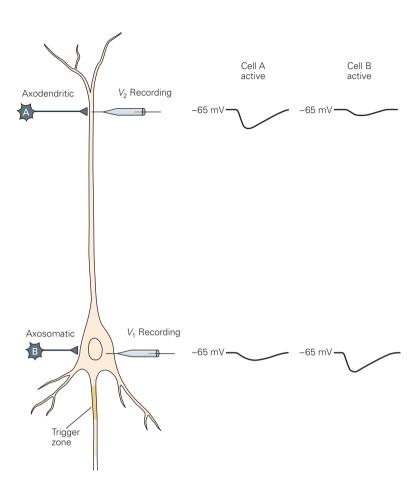

the amount of transmitter released from the presynaptic terminals (see Chapter 12).

The location of inhibitory inputs in relation to excitatory ones is critical for the effectiveness of the inhibitory stimuli. Inhibitory shunting is more significant when initiated at the cell body near the axon hillock. The depolarization produced by an excitatory current from a dendrite must pass through the cell body as it moves toward the axon initial segment. Inhibitory actions at the cell body open Cl⁻ channels, thus increasing Cl⁻ conductance and reducing by shunting much of the depolarization produced by the spreading excitatory current. As a result, the influence of the excitatory current on the membrane potential at the trigger zone is strongly curtailed (Figure 10-17). In contrast, inhibitory actions at a remote part of a dendrite are much less effective in shunting excitatory actions or in affecting the more distant trigger zone. Thus, it is not surprising that in the brain significant inhibitory input frequently occurs on the cell body of neurons.

Even though some excitatory inputs occur on dendritic shafts, close to 95% of all excitatory inputs in the brain terminate on dendritic spines, surprisingly avoiding dendritic shafts (see Figure 10-3). Although the function of spines is not completely understood, their thin necks provide a barrier to diffusion of various signaling molecules from the spine head to the dendritic shaft. As a result a relatively small Ca²⁺ current through the NMDA receptors can lead to a relatively large increase in [Ca2+] that is localized to the head of the individual spine that is synaptically activated (Figure 10–18A). Moreover, because action potentials can backpropagate from the cell body to the dendrites (see below), spines also serve as sites at which information about presynaptic and postsynaptic activity is integrated. Indeed, when a backpropagating action potential is paired with presynaptic stimulation, the spine Ca²⁺ signal is greater than the linear sum of the individual Ca2+ signals from synaptic stimulation alone or action potential stimulation alone. This "supralinearity" is specific to the activated spine and occurs because depolarization during the action potential causes Mg²⁺ to be expelled from the NMDA receptor, allowing it to conduct Ca²⁺ into the spine (see Figure 10–5). The resultant Ca²⁺ accumulation thus provides, at an individual synapse, a biochemical detector of the near simultaneity of the input (EPSP) and output (backpropagating action potential), which is thought to be a key requirement of memory storage.

As the thin spine neck, at least partly, restricts the rise in Ca²⁺, and thus long-term plasticity, to the spine that receives the synaptic input, spines also ensure that activity-dependent changes in synaptic function, and

Figure 10-17 The effect of an inhibitory current in the postsynaptic neuron depends on the distance the current travels from the synapse to the cell's trigger zone. In this hypothetical experiment the inputs from inhibitory axosomatic and axodendritic synapses are compared by recording from both the cell body (V_1) and the dendrite (V_2) of the postsynaptic cell. Stimulating the axosomatic synapse from presynaptic cell B produces a large IPSP in the cell body. Because the synaptic potential is initiated in the cell body it will undergo little decrement before arriving at the trigger zone in the initial segment of the axon. The IPSP decays as it propagates up the dendrite, producing only a small hyperpolarization at the site of dendritic recording. Stimulating the axodendritic synapse from presynaptic cell A produces a large local IPSP in the dendrite but only a small IPSP in the cell body because the synaptic potential decays as it propagates down the dendrite to the cell body. Thus the axosomatic IPSP is more effective than the axodendritic IPSP in inhibiting action potential firing in the postsynaptic cell.

thus memory storage, are restricted to the synapses that are activated. The ability of spines to implement such synapse-specific local learning rules may be of fundamental importance for the ability of neural networks to store meaningful information (see Appendix E). Finally, the local synaptic potentials in some spines are filtered as they propagate through the spine neck and enter the dendrite, reducing the size of the EPSP at the soma. The regulation of this electrical filtering could control the efficacy with which local EPSPs are conducted to the soma.

An Overall View

The past several years have seen a remarkable growth in our understanding of the diversity of molecules and mechanisms underlying the postsynaptic responses of neurons in the central nervous system to transmitter released from their presynaptic inputs. Nonetheless, nearly all fast synaptic actions in the brain are mediated by only three main amino acid neurotransmitters: the

excitatory transmitter glutamate and the inhibitory transmitters GABA and glycine. These produce rapid changes in the postsynaptic membrane potential by acting on specific classes of ligand-gated channels, known as ionotropic receptors. Glutamate depolarizes a postsynaptic cell by acting on three types of ionotropic receptors: the kainate, AMPA, and NMDA receptors. In addition, glutamate acts on metabotropic receptors to produce slower modulatory synaptic actions that can be either excitatory or inhibitory. The fast inhibitory transmitters hyperpolarize cells by acting on GABA_A receptors or glycine receptors. GABA also binds to inhibitory metabotropic GABA_B receptors,

The inhibitory $GABA_A$ and glycine receptors belong to the same superfamily of receptors as do the excitatory nicotinic ACh receptors present at the neuromuscular junction. They are composed of five homologous subunits, with each subunit containing four membrane-spanning α -helixes. The three types of glutamate receptors belong to a separate receptor gene family. They are composed of four homologous subunits, with each subunit containing two extracellular ligand binding

regions and a transmembrane domain containing three membrane-spanning α -helixes and a reentrant P-loop that forms the selectivity filter of the channel.

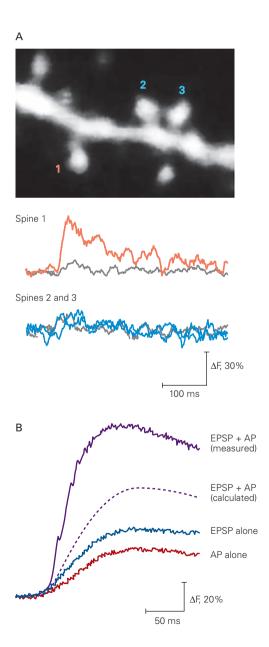

Despite the fact that fast synaptic transmission in the brain depends on only three major neurotransmitters acting on five main classes of ionotropic receptors, there is an enormous diversity in the postsynaptic properties of synapses in the brain. This is due, in part, to the presence of a large number of subtypes of the different receptors, resulting from the presence of multiple isoforms of receptor subunits encoded by distinct but related genes. Further diversity is generated through posttranscriptional processing, including differential RNA splicing and RNA editing. For GABA_A receptors alone it has been estimated that there is a potential for the existence of up to 800 different receptor subtypes due to combinatorial arrangements of the different subunit isoforms, although it is likely that far fewer are actually generated in the brain.

Clearly, a major challenge is the identification of which receptor subunit combinations actually exist in the brain and where those subunits are located. Although this is a daunting task, the potential payoff is great, offering the possibility of subtype-specific drugs

Figure 10–18 Dendritic spines compartmentalize calcium influx through NMDA receptors.

A. This fluorescence image of a hippocampal CA1 pyramidal neuron filled with a calcium-sensitive dye shows the outline of a dendritic shaft with several spines. When the dye binds Ca^{2^+} its fluorescence intensity increases. The traces plot fluorescence intensity as a function of time following the extracellular stimulation of the presynaptic axon. Spine 1 shows a large, rapid fluorescence increase (ΔF) in response to synaptic stimulation (red trace), reflecting Ca^{2^+} influx through the NMDA receptors. In contrast, there is little change in the fluorescence intensity in the neighboring dendrite shaft (grey trace), showing that Ca^{2^+} accumulation is restricted to the head of the spine. Spines 2 and 3 show little increase in fluorescence in response to synaptic stimulation because their presynaptic axons were not activated by the external stimulus. (Reproduced, with permission, from Lang et al. 2004.)

B. Calcium accumulation is greatest in spines when synaptic stimulation is paired with postsynaptic action potentials. The vertical axis is proportional to the intracellular Ca^{2+} concentration in a dendritic spine. The Ca^{2+} signal generated when an EPSP and a backpropagating action potential are evoked at the same time (EPSP + AP [measured]) is greater than the expected sum of the individual Ca^{2+} signals (EPSP + AP [calculated]) when either an EPSP or a backpropagating action potential (AP) is evoked alone. (Adapted, with permission, from Yuste and Denk, 1995.)

that produce highly specific actions. For example, whereas compounds that produce a nonspecific blockade of all types of GABA_A receptors lead to excess excitation and seizures, a drug that selectively blocks the subtype of GABA_A receptor containing the $\alpha 5$ -subunit has a beneficial effect on memory storage. A different drug that activates the GABA_A $\alpha 2/\alpha 3$ -subtype of receptors alleviates neuropathic pain.

As we have seen in this chapter and will return to throughout the book, one of the key properties of neuronal synapses is that their function can be modulated by experience. Some forms of synaptic plasticity involve long-term changes in receptor expression. One of the best characterized examples of activity-dependent synaptic plasticity depends on the properties of the NMDA receptors, which conduct Ca²⁺ into a postsynaptic cell when two criteria are met: Glutamate must be released from the presynaptic terminal and the postsynaptic neuron must be sufficiently depolarized to expel Mg²⁺ from the pore of the receptor through electrostatic repulsion. In normal amounts, Ca²⁺ triggers signaling pathways that enhance excitatory synaptic transmission, a process essential for certain types of memory (see Chapters 66 and 67). In excess, as occurs during stroke and certain neurodegenerative diseases, Ca2+ leads to neuronal death and brain damage.

Another key aspect of synaptic transmission in the CNS is the fact that individual excitatory or inhibitory inputs normally produce relatively small changes in a neuron's membrane potential. A neuron must therefore integrate information from thousands of excitatory and inhibitory inputs before deciding whether the threshold for an action potential (-55 mV) has been reached. The summation of these inputs within a single cell depends critically on the cell's passive properties, namely on its time and length constants. Moreover, a synapse's location is critically important to its efficacy. Excitatory synapses tend to be located on spines on neuronal dendrites, whereas inhibitory synapses predominate on the cell body, where they can effectively interrupt and override the excitatory inputs traveling down the cell's dendrites to the soma. The final summing of inputs to the cell is made at the axon initial segment, which contains the highest density of Na⁺ channels in the cell and thus has the lowest threshold for spike initiation. The consequences of mixed excitatory and inhibitory inputs in neural networks is discussed in Appendix E.

Much of the discussion in this chapter has been based on the schematic model of the neuron outlined in Chapter 2. According to this model, the dendritic tree is specialized as the receptive pole of the neuron, the axon is the signal-conducting portion, and the axon terminal is the transmitting pole. This model implies that the neuron, the signaling unit of the nervous system, merely sends and receives information. In reality, neurons in most brain regions are more complex. As we have seen in this chapter, active conductances allow dendrites to propagate action potentials, which interact with synaptic events to produce long-lasting changes in synaptic transmission. Moreover, dendritic spines appear ideally suited to implement inputspecific learning rules. Thus, our current view is that dendrites are complex, integrative compartments in neurons that can powerfully affect the propagation of synaptic potentials to the cell body and the relay of activity-dependent information from the cell body and initial segment back to synapses on the dendrites. Although crucial to neuronal integration, the electrical properties of dendrites and spines remain rather poorly understood and are an area of active investigation. In fact, as we shall see when considering the sensory and motor systems, the integrative properties of neurons in many brain regions allow the neurons to perform essential transformations on their inputs, rather than serve as simple relay stations.

An Overall View

aptic receptors produces a postsynaptic potential either directly, by opening ion channels, or indirectly, by altering ion channel activity through changes in the postsynaptic cell's biochemical state. As we saw in Chapter 8, the type of action depends on the type of receptor. Activation of *ionotropic receptors* directly opens ion channels that are part of the receptor macromolecule itself. In contrast, activation of *metabotropic receptors* regulates the opening of ion channels indirectly through biochemical signaling pathways. The receptor and ion channels that are affected are distinct macromolecules (Figure 11–1).

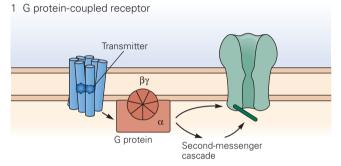

Whereas the action of ionotropic receptors is fast and brief, metabotropic receptors produce effects that begin slowly and persist for long periods, ranging from hundreds of milliseconds to many minutes. The two types of receptors also differ in their functions. Ionotropic receptors *mediate* behaviors, from simple reflexes to complex cognitive processes. Metabotropic receptors *modulate* behaviors; they modify reflex strength, help focus attention, set emotional states, and contribute to long-lasting changes in neural circuits that underlie learning and memory. Metabotropic receptors are responsible for many of the actions of transmitters, hormones, and growth factors.

Ionotropic receptors change the balance of charge across the neuron's membrane quickly. As we have seen, this change is local at first but is propagated as an action potential along the axon if the change in membrane potential is suprathreshold. Activation of metabotropic receptors also begins as a local action that can spread to a wider region of the cell. A neurotransmitter reacting with a metabotropic receptor activates proteins that in

A Direct gating

B Indirect gating

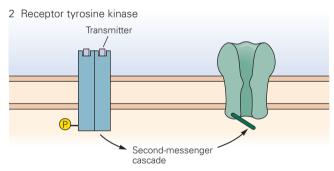

Figure 11–1 Neurotransmitter actions can be divided into two groups according to the way in which receptor and effector functions are coupled.

A. Direct transmitter actions are produced by ionotropic receptors, ligand-gated channels in which the receptor and ion channel are domains formed by a single macromolecule. The binding of transmitter to the receptor on the extracellular aspect of the protein directly opens the ion channel embedded in the cell membrane.

B. Indirect transmitter actions are caused by binding of transmitter to metabotropic receptors that are separate macromolecules from the ion channels that they regulate. There are two families of these receptors. 1. G protein-coupled receptors activate guanosine triphosphate (GTP)-binding proteins that engage a second-messenger cascade or act directly on ion channels.

2. Receptor tyrosine kinases initiate a cascade of protein phosphorylation reactions, beginning with autophosphorylation of the kinase itself on tyrosine residues.

turn activate effector enzymes. The effector enzymes then often produce second-messenger molecules that can diffuse within a cell to activate still other enzymes that catalyze modifications of a variety of target proteins, greatly changing their activities.

There are two major families of metabotropic receptors: G protein-coupled receptors and receptor tyrosine kinases. We first describe the G protein-coupled receptor family and later discuss the receptor tyrosine kinase family.

The G protein-coupled receptors are coupled to an effector by a trimeric guanine nucleotide-binding protein, or G protein (Figure 11–1B). This receptor family contains α - and β -adrenergic receptors for nore-pinephrine, muscarinic acetylcholine (ACh) receptors, γ -aminobutyric acid B (GABA_B) receptors, certain glutamate and serotonin receptors, all receptors for dopamine, receptors for neuropeptides, odorant receptors, rhodopsin (the protein that reacts to light, initiating visual signals, see Chapter 26), and many others. Many of these receptors are thought to be involved in neurological and psychiatric disease and are key targets for the actions of important classes of therapeutic drugs.

G protein-coupled receptors activate a variety of effectors. Typically the effector is an enzyme that produces a diffusible second messenger. These second messengers in turn trigger a biochemical cascade, either by activating specific protein kinases that phosphorylate the hydroxyl group of specific serine or threonine residues in various proteins or by mobilizing Ca²⁺ ions from intracellular stores, thus initiating reactions that change the cell's biochemical state. In some instances the G protein or the second messenger act directly on an ion channel.

The Cyclic AMP Pathway Is the Best Understood Second-Messenger Signaling Cascade Initiated by G Protein-Coupled Receptors

The adenosine 3',5'-cyclic monophosphate (cyclic AMP or cAMP) pathway is a prototypic example of a second-messenger cascade. It was the first second-messenger pathway to be discovered, and our conception of other second-messenger pathways is based on it.

The binding of transmitter to receptors linked to the cAMP cascade first activates a specific G protein, G_s (named for its action to *stimulate* cAMP synthesis). In its resting state G_s , like all G proteins, binds a molecule of guanosine diphosphate (GDP). The interaction of G_s with a ligand-bound receptor promotes the exchange

Receptor Transmitter G_s protein Adenylyl cyclase Extracellular side Cytoplasmic side -GDP GTP

Transmitter binding alters conformation of receptor, exposing binding site for \mathbf{G}_{s} protein.

Diffusion in the bilayer leads to association of transmitter receptor complex with ${\rm G_s}$ protein, thereby activating it for GTP-GDP exchange.

Displacement of GDP by GTP causes the $\alpha\text{-subunit}$ to dissociate from the G_s complex, exposing a binding site for adenylyl cyclase on the $\alpha\text{-subunit}.$

The α -subunit binds to and activates the cyclase to produce many molecules of cAMP.

Hydrolysis of the GTP by the $\alpha\textsc{-subunit}$ returns the subunit to its original conformation, causing it to dissociate from the cyclase (which becomes inactive) and reassociate with the $\beta\gamma$ complex.

The activation of the cyclase is repeated until the dissociation of transmitter returns the receptor to its original conformation.

of the bound GDP for guanosine triphosphate (GTP), leading to a conformational change that activates the G protein. In its activated state G_s stimulates the integral membrane protein adenylyl cyclase to catalyze the conversion of adenosine triphosphate (ATP) to cAMP. When associated with the cyclase, G_s also acts as a GTPase, hydrolyzing its bound GTP to GDP. When GTP is hydrolyzed, the G protein becomes inactive and dissociates from the cyclase, thereby stopping the synthesis of cAMP (Figure 11–2). Typically, a G_s protein remains active for a few seconds before its bound GTP is hydrolyzed.

Once a G protein-coupled receptor binds a ligand, it can interact sequentially with more than one G protein macromolecule. As a result, the sequential binding of relatively few molecules of transmitter to a small number of receptors can activate a large number of cyclase complexes. The signal is further amplified in the next step in the cAMP cascade, the activation of the protein kinase.

The major target of cAMP in most cells is the cAMP-dependent protein kinase (also called protein kinase A or PKA). This kinase, identified and characterized by Edward Krebs and colleagues, is a heterotetrameric enzyme consisting of a dimer of two regulatory (R) subunits and two catalytic (C) subunits. In the absence of cAMP the R subunits bind to and inhibit the C subunits. In the presence of cAMP each R subunit binds two molecules of cAMP, leading to a conformational change that causes the R and C subunits to dissociate (Figure 11–3). Dissociation frees the C subunits to transfer the γ -phosphoryl group of ATP to the hydroxyl groups of specific serine and threonine residues in substrate proteins.

Protein kinase A is distantly related through evolution to other serine and threonine protein kinases that we shall consider: the Ca²⁺/calmodulin-dependent protein kinases and protein kinase C. These kinases also have regulatory and catalytic domains, but both domains are within the same polypeptide molecule (see Figure 11–6).

Figure 11–2 The cAMP cycle. (Opposite) The binding of a transmitter to certain metabotropic receptors activates the stimulatory G protein (G_s). The G protein is a heterotrimer consisting of α -, β -, and γ -subunits. The β - and γ -subunits form a unit that binds tightly to the membrane. In its resting state the α -subunit of G_s, termed α_s , binds a molecule of guanosine diphosphate (GDP). When activated by its interaction with a ligand-bound receptor, the GDP bound to α_s is exchanged for guanosine triphosphate (GTP), causing α_s to functionally dissociate from the $\beta\gamma$ complex. Next α_s associates with an intracellular domain of adenylyl cyclase, thereby activating the enzyme

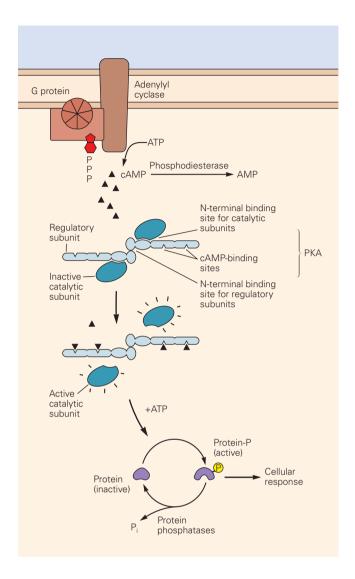

In addition to blocking enzymatic activity, the R subunits of PKA also target the C subunits to distinct sites within cells. Human PKA has two types of R subunits, each with two subtypes: $R_{I\alpha'}$ $R_{I\beta'}$ $R_{II\alpha'}$ and $R_{II\beta}$. The genes for each are distinct but derive from a common ancestor. The two R subunits in a molecule of PKA are present as a dimer, formed when the R subunits are synthesized. Because the dimer never separates, hybrid types of the kinase do not exist in the cell. This is functionally important because the types have different properties. For example, type II PKA (containing R_{II} -type subunits) is targeted to the membrane by A kinase attachment proteins (AKAPs). One AKAP targets PKA to the N-methyl-D-aspartate (NMDA)-type glutamate receptor by binding both PKA and the postsynaptic density protein PSD-95, which binds to the cytoplasmic tail of the NMDA receptor (see Chapter 10). In addition, this AKAP also binds a protein phosphatase, which removes the phosphate group from substrate proteins (see Figure 11–14). By localizing PKA and other signaling components near their substrate, AKAPs form local signaling complexes that increase the specificity, speed, and efficiency of second-messenger cascades. Because AKAPs have only a weak affinity for R_{τ} subunits, most type I PKA is free in the cytoplasm.

Kinases can only phosphorylate proteins on serine and threonine residues that are embedded within a context of specific *phosphorylation consensus sequences* of amino acids. For example, phosphorylation by PKA usually requires a sequence of two contiguous basic amino acids—either lysine or arginine—followed by any amino acid, and then by the serine or threonine residue that is phosphorylated (for example, Arg-Arg-Ala-Thr).

Several important protein substrates for PKA have been identified in neurons. These include voltage-gated and ligand-gated ion channels, synaptic vesicle proteins, enzymes involved in transmitter biosynthesis, and proteins that regulate gene transcription. As a result, the cAMP pathway has widespread effects on the electrophysiological and biochemical properties of neurons. We shall consider some of these actions later in this chapter.

to produce cAMP from adenosine triphosphate (ATP). When bound to the cyclase, $\alpha_{\rm s}$ is a GTPase. The hydrolysis of GTP to GDP and inorganic phosphate (P_i) leads to the dissociation of $\alpha_{\rm s}$ from the cyclase and its reassociation with the $\beta\gamma$ complex. The cyclase then stops producing the second messenger. At some point during this cycle the transmitter dissociates from the receptor. The system returns to an inactive state when the transmitter-binding site on the receptor is empty, the three subunits of the G protein reassociate, and the guanine nucleotide-binding site on the α -subunit is occupied by GDP. (Adapted, with permission, from Alberts et al. 1994.)

Figure 11–3 The cAMP pathway activates protein kinase A. Adenylyl cyclase converts adenosine triphosphate (ATP) into cAMP. Four cAMP molecules bind to the two regulatory subunits of the protein kinase A (PKA), liberating the two catalytic subunits, which are then free to phosphorylate specific substrate proteins on certain serine or threonine residues, thereby producing a cellular response. Two kinds of enzymes regulate this pathway. Phosphodiesterases convert cAMP to adenosine monophosphate (which is inactive), and protein phosphatases remove phosphate groups (P) from the substrate proteins, releasing inorganic phosphate, P, (see also Figure 11–14).

The Second-Messenger Pathways Initiated by G Protein-Coupled Receptors Share a Common Molecular Logic

Approximately 800 of the roughly 23,000 genes thought to comprise the human genome code for G protein-coupled receptors. Although many of these are odorant receptors in olfactory neurons (see Chapter 32), many others are receptors for well-characterized neurotransmitters used throughout the nervous system. Despite their enormous diversity, all G protein-coupled receptors consist of a single polypeptide with seven characteristic membrane-spanning regions (serpentine receptors) (Figure 11–4).

The number of substances that act as second messengers in synaptic transmission is much fewer than the number of transmitters. Approximately 100 substances serve as transmitters; each can activate several types of receptors on the cell surface. The few second messengers that have been well characterized fall into two categories, intracellular and transcellular. Intracellular messengers are molecules whose actions are confined to the cell in which they are produced. Transcellular messengers are molecules that can readily cross the cell membrane and thus can leave the cell in which they are produced to act as intercellular signals, or first messengers, on neighboring cells.

A Family of G Proteins Activates Distinct Second-Messenger Pathways

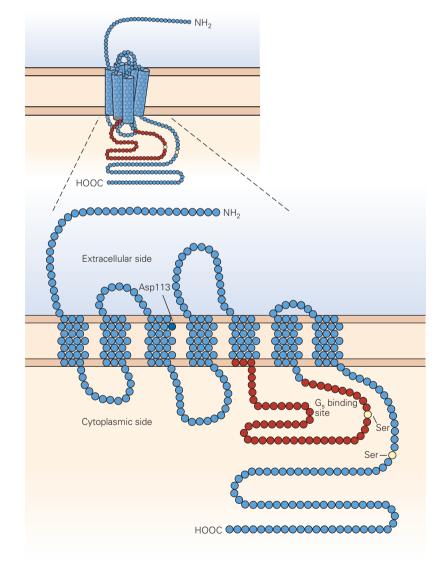

The first G protein, G_s (where "s" stands for stimulatory), was identified more than 30 years ago by

Martin Rodbell, Al Gilman, and their colleagues. Since that time a large family of G proteins has been identified. The G proteins are associated with the inner leaflet of the plasma membrane, where they interact with G protein-coupled receptors.

The G proteins that couple receptor activation to intracellular effectors are trimers that consist of three subunits: α , β , and γ (Figure 11–2). The α -subunit is only loosely associated with the membrane and is usually the agent that couples the receptor to its primary effector enzyme. The β - and γ -subunits form a strongly bound complex that is more tightly associated with the membrane. As we shall learn later in this chapter, the $\beta\gamma$ complex of G proteins can also regulate the activity of certain ion channels directly.

Approximately 20 types of α -subunits have been identified, 5 types of β -subunits, and 12 types of γ -subunits. G proteins with different α -subunits couple different classes of receptors and effectors, and therefore have different physiological actions. The β -adrenergic receptor activates adenylyl cyclase by acting on G_s proteins; these contain the α_s type of α -subunit. Some muscarinic ACh receptors inhibit the cyclase by acting on G_s proteins (where "i" stands for inhibitory); these contain the α_s type subunit. Still other G proteins ($G_{q/11}$ proteins, which contain α_q - or α_{11} -subunits) activate phospholipase C and probably other signal transduction mechanisms not yet identified. The G_o protein, which contains the α_o -subunit, is expressed at particularly high levels in the brain. Compared with other organs

Figure 11-4 G protein-coupled receptors contain seven membrane-spanning **domains.** The β_2 -adrenergic receptor shown here is representative of G protein-coupled receptors, including the β_1 -adrenergic and muscarinic acetylcholine (ACh) receptors and rhodopsin. It consists of a single subunit with an extracellular amino terminus, intracellular carboxy terminus, and seven membranespanning α -helixes. The binding site for the neurotransmitter lies in a cleft in the receptor formed by the transmembrane helixes. The amino acid residue aspartic acid (Asp)-113 participates in binding. The part of the receptor indicated in brown associates with G protein α -subunits. Two serine (Ser) residues in the intracellular carboxy-terminal tail are sites for phosphorylation by specific receptor kinases, which helps inactivate the receptor. (Adapted, with permission, from Frielle et al. 1989.)

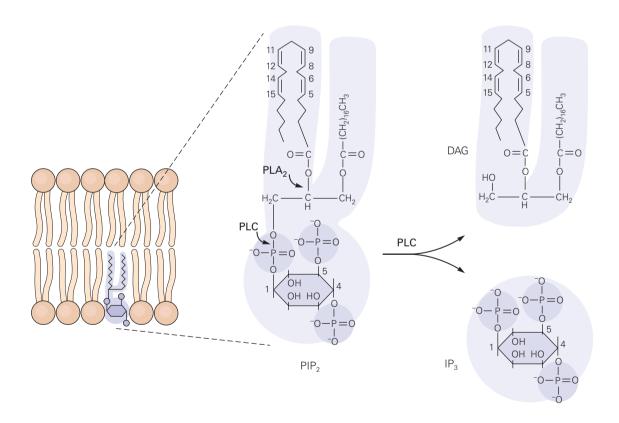

of the body, the brain contains an exceptionally large variety of G proteins. Even so, because of the limited number of classes of G proteins, one type of G protein can often be activated by different classes of receptors.

The known effector targets for G proteins are more limited than the types of G proteins. Important effectors include certain ion channels that are activated by the $\beta\gamma$ complex, adenylyl cyclase in the cAMP pathway, phospholipase C in the diacylglycerol-inositol polyphosphate pathway, and phospholipase A_2 in the arachidonic acid pathway. Each of these effectors (except for the ion channels) initiates changes in specific target proteins within the cell, either by generating second messengers that bind to the target protein or by activating a protein kinase that phosphorylates it. Despite their differences, second-messenger pathways activated by G protein signaling share a common design (Figure 11–5).

Hydrolysis of Phospholipids by Phospholipase C Produces Two Important Second Messengers, IP₃ and Diacylglycerol

Many important second messengers are generated through the hydrolysis of phospholipids in the inner leaflet of the plasma membrane. This hydrolysis is catalyzed by three enzymes—phospholipase C, phospholipase D, and phospholipase A₂—named for the ester bonds they hydrolyze in the phospholipid. The phospholipases each can be activated by different G proteins coupled to different receptors.

The most commonly hydrolyzed phospholipid is phosphatidylinositol 4,5-bisphosphate (PIP₂), which typically contains the fatty acid stearate esterified to the glycerol backbone in the first position and the unsaturated fatty acid arachidonate in the second:

Activation of receptors coupled to G_q or G_{11} stimulates phospholipase C, which leads to the hydrolysis of PIP_2 (specifically the phosphodiester bond that links the glycerol backbone to the polar head group) and production of two second messengers, diacylglycerol

(DAG) and inositol 1,4,5-trisphosphate (IP₃). DAG, which is hydrophobic, remains in the membrane when formed, where it recruits the cytoplasmic protein kinase C (PKC). PKC and DAG together with certain membrane phospholipids form an active complex that can

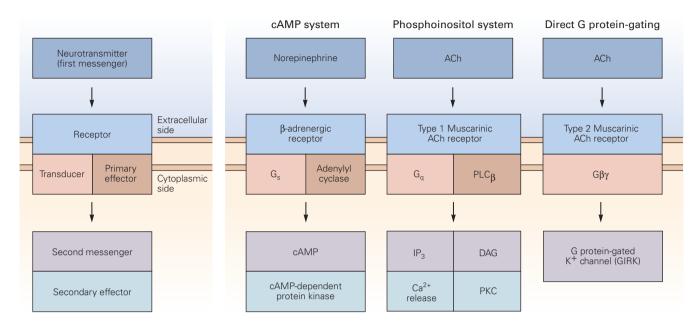

Figure 11–5 Synaptic second-messenger systems involving G protein coupling follow a common sequence. The signal transduction pathways illustrated here involve similar steps (left). Chemical transmitters arriving at receptor molecules in the plasma membrane activate a closely related family of G proteins (the transducers) that activate different enzymes or channels (the primary effectors). The activated enzymes produce a second messenger that activates a secondary effector or acts directly on a target (or regulatory) protein.

cAMP system. This pathway can be activated by a transmitter-bound β -adrenergic receptor, which acts through the G_s protein α_s -subunit to activate adenylyl cyclase. Adenylyl cyclase produces the second messenger cAMP, which activates PKA. The G protein here is termed G_s because it stimulates the cyclase. Some receptors activate a G_i protein that inhibits the cyclase.

Phosphoinositol system. This pathway, activated by a type 1 muscarinic acetylcholine (ACh) receptor, uses the G_a or G_{11} type

of G protein (with $\alpha_{\rm q}$ - or $\alpha_{\rm 11}$ -subunits, respectively) to activate a primary effector, phospholipase C β (PLC $_{\beta}$). This enzyme hydrolyzes the phospholipid, phosphatidylinositol 4,5-bisphosphate (PIP $_{\rm 2}$), yielding a pair of second messengers: diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP $_{\rm 3}$). In turn, IP $_{\rm 3}$ releases Ca $^{\rm 2+}$ from internal stores, whereas DAG activates protein kinase C (PKC). The drop in membrane PIP $_{\rm 2}$ levels can directly alter the activity of some ion channels.

Direct G protein-gating. This pathway represents the simplest synaptic mechanism for G protein-coupled receptor action. Acetylcholine (ACh) acting on type 2 muscarinic receptors activates the $G_{_{\parallel}}$ protein, leading to functional dissociation of the $\alpha_{_{\parallel}}$ -subunit and $\beta\gamma$ complex. The $\beta\gamma$ complex interacts directly with a G protein-gated inward-rectifying K+channel (GIRK), leading to channel opening and membrane hyperpolarization.

phosphorylate many protein substrates in the cell, both membrane-associated and cytoplasmic (Figure 11–6A). Activation of some isoforms of PKC requires elevated levels of cytoplasmic Ca²⁺ in addition to DAG (Box 11–1).

The second product of the phospholipase C pathway, IP_3 , stimulates the release of Ca^{2+} from intracellular membrane stores in the lumen of the smooth endoplasmic reticulum. The membrane of the reticulum contains a large integral membrane macromolecule, the IP_3 receptor, which forms both a receptor for IP_3 on its cytoplasmic surface and a Ca^{2+} -permeant channel that spans the membrane of the reticulum. When this macromolecule binds IP_3 the channel opens, releasing Ca^{2+} into the cytoplasm (Figure 11–6A).

The increase in intracellular Ca²⁺ triggers many biochemical reactions and opens calcium-gated channels in

the plasma membrane. Calcium can also act as a second messenger to trigger the release of additional Ca²⁺ from internal stores by binding to another integral protein in the membrane of the smooth endoplasmic reticulum, the ryanodine receptor (so called because it binds the plant alkaloid ryanodine, which inhibits the receptor; in contrast, caffeine opens the ryanodine receptor). Like the IP₃ receptor to which it is distantly related, the ryanodine receptor forms a Ca²⁺-permeant channel that spans the reticulum membrane; however, cytoplasmic Ca²⁺, not IP₃, gates the ryanodine receptor-channel.

Calcium often acts by binding to the small cytoplasmic protein calmodulin. An important function of the calcium/calmodulin complex is to activate the Ca²⁺/calmodulin-dependent protein kinase (CaM kinase). This enzyme is a complex of many similar subunits, each

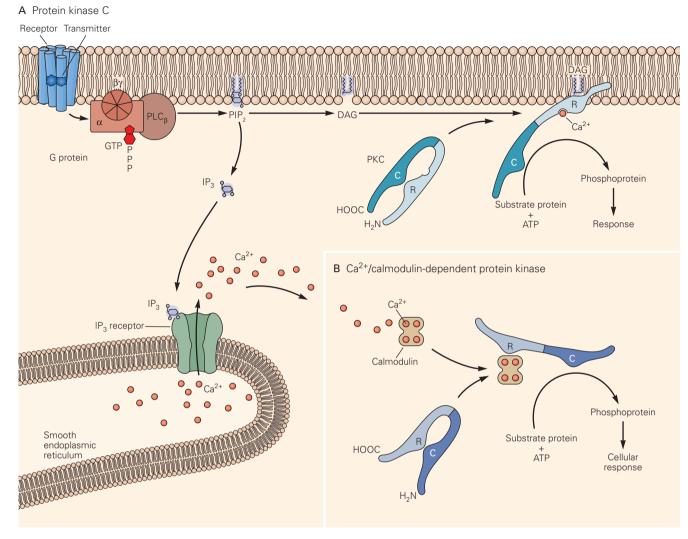

Figure 11–6 Hydrolysis of phospholipids in the cell membrane activates three major second-messenger cascades.

A. The binding of transmitter to a receptor activates a G protein that activates phospholipase C β (PLC $_\beta$). This enzyme cleaves phosphatidylinositol 4,5-bisphosphate (PIP $_2$) into the second messengers, inositol 1,4,5-trisphosphate (IP $_3$) and diacylglycerol (DAG). IP $_3$ is water-soluble and diffuses into the cytoplasm, where it binds to a receptor-channel on the smooth endoplasmic reticulum, the IP $_3$ receptor, to release Ca $^{2+}$ from internal stores. DAG remains in the membrane, where it activates protein kinase C (PKC). Membrane phospholipid is also a necessary cofactor for PKC activation. Some isoforms of PKC also require Ca $^{2+}$ for activation. PKC is composed of a single protein

molecule that has both a regulatory domain that binds DAG and a catalytic domain that phosphorylates proteins on serine or threonine residues.

B. The Ca²+/calmodulin-dependent protein kinase is activated when Ca²+ binds to calmodulin. The Ca²+/calmodulin complex then binds to a regulatory domain of the kinase, causing its activation. The kinase is composed of many similar subunits (only one of which is shown here), each having both regulatory and catalytic functions. The catalytic domain phosphorylates proteins on serine or threonine residues. (ATP, adenosine triphosphate; C, catalytic subunit; COOH, carboxy terminus; H_2N , amino terminus; R, regulatory subunit.)

containing both regulatory and catalytic domains within the same polypeptide chain. When the Ca²⁺/calmodulin complex is absent, the C-terminal regulatory domain of the kinase binds and inactivates the catalytic portion. Binding to the Ca²⁺/calmodulin complex causes

conformational changes of the kinase molecule that unfetter the catalytic domain for action (Figure 11–6B). Once activated, CaM kinase can phosphorylate itself through intramolecular reactions at many sites in the molecule. Autophosphorylation has an important functional effect:

It converts the enzyme into a form that is independent of Ca²⁺/calmodulin and therefore persistently active even in the absence of Ca²⁺.

Persistent activation of protein kinases is a general and important mechanism for maintaining biochemical processes underlying long-term changes in synaptic function associated with certain forms of memory. In addition to the persistent activation of Ca2+/calmodulin-dependent protein kinase, PKA can also become persistently active following a transient increase in cAMP, because of the enzymatic degradation of its regulatory subunits through the ubiquitin pathway. The decline in regulatory subunit concentration results in the longlasting presence of free catalytic subunits, even after cAMP levels have declined, leading to the continued phosphorylation of substrate proteins. PKC can also become persistently active through proteolytic cleavage of its regulatory and catalytic domains or expression of a PKC isoform that lacks a regulatory domain.

Hydrolysis of Phospholipids by Phospholipase A_2 Liberates Arachidonic Acid to Produce Other Second Messengers

Phospholipase A_2 hydrolyzes phospholipids distinct from PIP_2 by cleaving the fatty acyl bond between the 2' position of the glycerol backbone and arachidonic

acid. This releases arachidonic acid, which is then converted through enzymatic action to one of a family of active metabolites called *eicosanoids*, so called because of their 20 (Greek *eicosa*) carbon atoms.

Three types of enzymes metabolize arachidonic acid: (1) cyclooxygenases, which produce prostaglandins and thromboxanes; (2) several lipoxygenases, which produce a variety of metabolites to be discussed below; and (3) the cytochrome P450 complex, which oxidizes arachidonic acid itself as well as cyclooxygenase and lipoxygenase metabolites (Figure 11–7).

Arachidonic acid and its metabolites are soluble in lipids and thus readily diffuse through membranes. Therefore, in addition to acting within the cell in which they are produced, these substances can act on neighboring cells, including a presynaptic neuron. In this way they act as transcellular synaptic messengers (discussed in the next section).

Synthesis of prostaglandins and thromboxanes in the brain is dramatically increased by nonspecific stimulation such as electroconvulsive shock, trauma, or acute cerebral ischemia (localized absence of blood). Many of the actions of prostaglandins are mediated in the plasma membrane by a family of G protein-coupled receptors. The members of this receptor family can activate or inhibit adenylyl cyclase or activate phospholipase C.

Box 11-1 Isoforms of Protein Kinase C

At least nine isoforms of protein kinase C (PKC) have been found in nervous tissue. Rather than having regulatory and catalytic functions in different subunits, like PKA, most PKC isoforms contain regulatory and catalytic domains in a single continuous polypeptide chain (see Figure 11–6A).

Two functionally interesting differences have thus far been found among these isoforms. The so-called major forms (α , $\beta_{I'}$, $\beta_{II'}$, and γ) all have a calcium-binding site and are activated by Ca²⁺ ions together with diacylglycerol. The minor forms (eg, δ , ϵ , and ζ) lack the calcium-binding domain, and therefore their activity is independent of Ca²⁺.

The second interesting difference is that, of the major forms, only PKC γ is activated by low concentrations of arachidonic acid, a membrane fatty acid, although all the isoforms respond to diacylglycerol or phorbol esters (plant toxins that bind to PKC and promote tumors).

With one exception, PKC isoforms also contain a site between the regulatory and catalytic domains that is sensitive to proteolysis. High levels of cytoplasmic Ca^{2+} can activate proteases that cleave PKC at this site, releasing a cytoplasmic form of PKC called protein kinase M (PKM). This protein fragment is constitutively active because it lacks the regulatory domain. As a result, elevations in Ca^{2+} can lead to prolonged activation of the kinase.

Long-lasting activation of PKC can also be produced through expression of the gene encoding PKC ζ . This isoform is unique in that it lacks a regulatory domain and is therefore constitutively active. Expression of PKC ζ produces persistent PKC activity in hippocampal neurons during the induction of long-term potentiation, which is thought to underlie certain forms of learning and memory in the hippocampus (see Chapter 67).

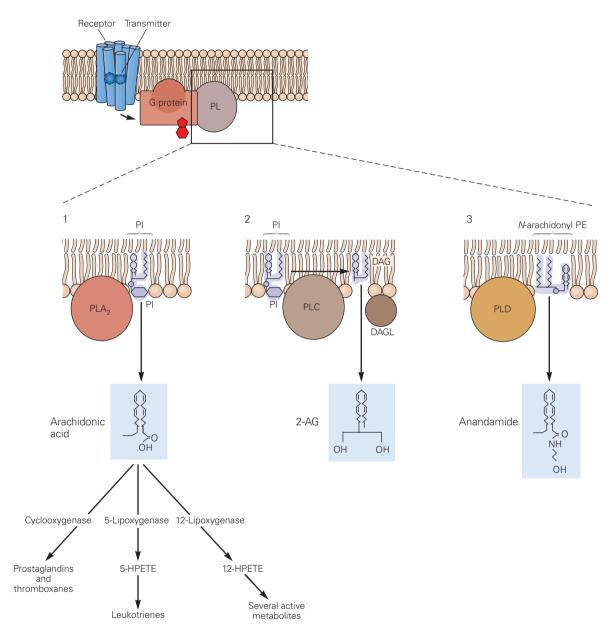

Figure 11–7 Three phospholipases generate distinct second messengers by hydrolysis of phospholipids containing arachidonic acid.

Pathway 1. Stimulation of G protein-coupled receptors leads to activation of phospholipase A_2 (PLA2) by the free $\beta\gamma$ subunit complex. Phospholipase A_2 hydrolyzes phosphatidylinositol (PI) in the plasma membrane, leading to the release of arachidonic acid, a 20-carbon fatty acid that is a component of many phospholipids. Once released, arachidonic acid is metabolized through several pathways, three of which are shown. The 12- and 5-lipoxygenase pathways both produce several active metabolites; the cyclooxygenase pathway produces prostaglandins and thromboxanes. Cyclooxygenase is inhibited by indomethacin, aspirin, and other nonsteroidal anti-inflammatory drugs. Arachidonic acid and many of its metabolites modulate the activity of certain ion channels.

Pathway 2. Other G proteins activate phospholipase C (PLC), which hydrolyzes PI in the membrane to generate DAG (see Figure 11–6). Hydrolysis of DAG by a second enzyme, diacylglycerol lipase (DAGL), leads to production of 2-arachidonylglycerol (2-AG), an endocannabinoid that is released from neuronal membranes and then activates G protein-coupled endocannabinoid receptors in the plasma membrane of other neighboring neurons.

Pathway 3. Elevation of intracellular Ca²⁺ activates phospholipase D (PLD), which hydrolyzes phospholipids that have an unusual polar head group containing arachidonic acid (*N*-arachidonylphosphatidylethanolamine [*N*-arachidonyl PE]). This action generates a second endocannabinoid termed anandamide (arachidonylethanolamide). (HPETE, hydroperoxyeicosatetraenoic acid.)

Lipoxygenases introduce an oxygen molecule into the arachidonic acid molecule, generating hydroper-oxyeicosatetraenoic acids (HPETEs). These metabolites are synthesized in response to depolarization of brain slices with high concentrations of extracellular K⁺, glutamate, or NMDA. The compounds 5-HPETE, 12-HPETE, and some of their downstream metabolites modulate certain ion channels. These metabolites may also be important in mediating pain sensation by activating transient receptor potential (TRP) ion channels in certain sensory neurons (see Chapter 5). They also can act as transcellular second messengers, a function that appears to be important for long-term synaptic changes in the hippocampus.

Transcellular Messengers Are Important for Regulating Presynaptic Function

Our understanding of the physiological importance of transcellular messengers is continuing to evolve. In addition to the lipoxygenase metabolites of arachidonic acid, two other important classes of transcellular messengers are the endocannabinoids and gases, both of which readily diffuse through the membrane into the extracellular space.

Endocannabinoids Are Derived from Arachidonic Acid

In the early 1990s researchers identified two types of G protein-coupled receptors, CB1 and CB2, which bind with high affinity the active compound in marijuana, Δ^9 -tetrahydrocannabinol (THC). Both classes of receptors are coupled to G_i and G_o types of G proteins.

The CB1 receptors are the most abundant type of G protein-coupled receptor in the brain and are found predominantly on axons and presynaptic terminals in the central and peripheral nervous systems. Activation of these receptors inhibits release of several types of neurotransmitters, including the inhibitory neurotransmitter GABA and the excitatory transmitter glutamate. The CB2 receptors are found mainly on lymphocytes, where they modulate the immune response.

The identification of the cannabinoid receptors led to the purification of their endogenous ligands, the endocannabinoids. Two major endocannabinoids have been identified. Anandamide (Sanskrit *ananda*, bliss) consists of arachidonic acid coupled to ethanolamine (arachidonylethanolamide); 2-arachidonylglycerol (2-AG) consists of arachidonic acid esterified at the 2 position of glycerol. Both are produced by the enzymatic hydrolysis of phospholipids containing arachidonic acid, a process that is

initiated either when certain G protein-coupled receptors are stimulated or the internal Ca²⁺ concentration is elevated (Figure 11–7). The two endocannabinoids bind to both CB1 and CB2 receptors.

Because the endocannabinoids are lipid metabolites that can diffuse through the membrane, they also can act as transcellular retrograde signals (Figure 11–8). Production of these metabolites is often stimulated in postsynaptic neurons by the increase in intracellular Ca²⁺ that results from postsynaptic excitation. Once produced, the endocannabinoids diffuse through the cell membrane to nearby presynaptic terminals, where they bind to CB1 receptors and inhibit transmitter release. In this manner the postsynaptic cell can control activity of the presynaptic neuron. There is now intense interest in understanding how the activation of these receptors in the brain leads to the various behavioral effects of marijuana.

The Gaseous Second Messengers, Nitric Oxide and Carbon Monoxide, Stimulate Cyclic GMP Synthesis

The two best studied gaseous transcellular messengers are nitric oxide (NO) and carbon monoxide (CO). Like other second messengers, NO and CO are not unique to neurons but operate in other cells of the body. For example, NO is a local hormone released from the endothelial cells of blood vessels, causing relaxation of the smooth muscle of vessel walls. Like the metabolites of arachidonic acid, NO and CO readily pass through cell membranes. They affect nearby cells without acting on a surface receptor, and they are extremely short-lived.

How do NO and CO produce their actions? Both gases stimulate the synthesis of guanosine 3′,5′-cyclic monophosphate (cyclic GMP or cGMP), which like cAMP is a cytoplasmic second messenger that activates a protein kinase. Specifically, NO and CO activate guanylyl cyclase, the enzyme that converts GTP to cGMP. There are two types of guanylyl cyclase. One is an integral membrane protein with an extracellular receptor domain and an intracellular catalytic domain that synthesizes cGMP. The other is cytoplasmic (soluble guanylyl cyclase) and is the isoform that is activated by NO.

Cyclic GMP has two major actions. It acts directly to open cyclic nucleotide-gated channels (important for phototransduction and olfactory signaling, as described in Chapters 26 and 32, respectively), and it activates the cGMP-dependent protein kinase (PKG). PKG differs from the cAMP-dependent protein kinase in that it is a single polypeptide with both regulatory (cGMP-binding) and catalytic domains, which are

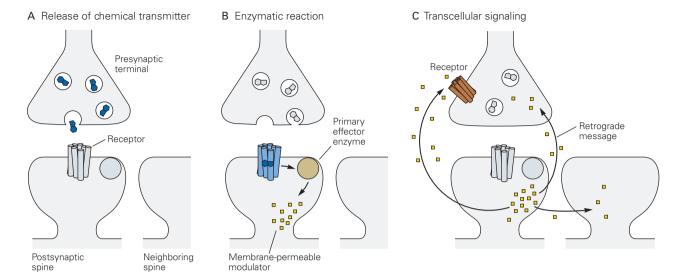

Figure 11–8 Transcellular signaling can occur from the postsynaptic neuron to the presynaptic neuron (retrograde transmission) and between postsynaptic cells. Until recently, synaptic signaling was thought to occur only from the presynaptic neuron to the postsynaptic cell. Transcellular signaling is initiated by a presynaptic signal. A presynaptic terminal releases a neurotransmitter at the synapse and that transmitter reacts with a G protein-coupled receptor in a postsynaptic dendritic spine (A). The receptor activates enzymes that produce a

membrane-permeable modulator (B). The modulator is released from the postsynaptic spine and diffuses to neighboring postsynaptic spines as well as presynaptic terminals (C). There it can produce either first-messenger effects, by acting on G protein-coupled receptors in the surface membrane, or second-messenger-like effects, by entering the cell to act within. This kind of modulator of the presynaptic terminal is called a retrograde messenger rather than a second messenger, and its action is called transcellular signaling.

homologous to regulatory and catalytic domains in other protein kinases.

Cyclic GMP-dependent phosphorylation of proteins is prominent in Purkinje cells of the cerebellum, large neurons with copiously branching dendrites. There the cGMP cascade is activated by NO produced and released from the presynaptic terminals of granule cell axons (the parallel fibers) that make excitatory synapses onto the Purkinje cells. This increase in cGMP in the Purkinje neuron reduces the response of the AMPA receptors to glutamate, thereby depressing fast excitatory transmission at the parallel fiber synapse.

A Family of Receptor Tyrosine Kinases Mediates Some Metabotropic Receptor Effects

The receptor tyrosine kinases comprise the second major family of receptors that gate ion channels indirectly. These receptors are integral membrane proteins composed of a single subunit with an extracellular ligand-binding domain connected to a cytoplasmic region by a single transmembrane segment. The cytoplasmic region contains a protein kinase domain that phosphorylates both itself (autophosphorylation) and

other proteins on tyrosine residues (Figure 11–9). This phosphorylation results in the activation of a large number of proteins, including other kinases that are capable of acting on ion channels.

The ligands for the receptor tyrosine kinases are peptide hormones, including epidermal growth factor (EGF), fibroblast growth factor (FGF), nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), and insulin. Cells also contain important nonreceptor cytoplasmic tyrosine kinases, such as the protooncogene *src*. These nonreceptor tyrosine kinases are often activated by interactions with receptor tyrosine kinases and are important in regulating growth and development.

Many (but not all) of the receptor tyrosine kinases exist as monomers in the plasma membrane in the absence of ligand. Ligand binding causes one receptor subunit to associate with another to form a homodimer thereby activating the intracellular kinase. Each monomer phosphorylates its counterpart at a tyrosine residue, an action that enables the kinase to phosphorylate other proteins. Like the serine and threonine protein kinases, tyrosine kinases regulate the activity of neuronal proteins they phosphorylate, including the activity of certain ion channels. Tyrosine kinases also activate an

isoform of phospholipase C, phospholipase C γ , which like PLC β , cleaves PIP₂ into IP₃ and diacylglycerol.

Receptor tyrosine kinases initiate cascades of reactions involving several adaptor proteins and other protein kinases that often lead to changes in gene transcription. The mitogen-activated protein kinases (MAPKs) are an important group of serine-threonine kinases that can be activated by a signaling cascade initiated by receptor tyrosine kinase stimulation. MAP kinases are activated by cascades of protein-kinase reactions (kinase kinases), each cascade specific to one of three types of MAP kinase: extracellular signal regulated kinase (ERK), p38 MAP kinase, and *c-Jun* N-terminal kinase (JNK).

MAP kinase signaling cascades are initiated when a specific adaptor protein binds to a phosphotyrosine

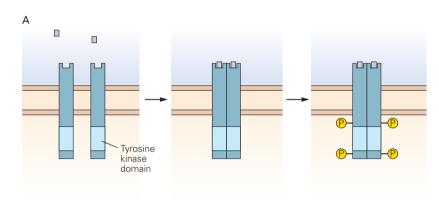

residue on the cytoplasmic tail of an activated receptor tyrosine kinase. The binding is mediated by the SH2 domain of the adaptor protein, named for the domain's homology to a region of src. A second adaptor protein domain, SH3 (named for its homology to another region of src), binds to proline-rich regions of effector proteins, thereby coupling the activated receptor to the effector. The signaling complex ultimately binds to a small monomeric GTP-binding protein (MW 20,000–40,000), such as Ras or one of its relatives. Ras was first identified because it acts as a protooncogene. These small GTP-binding proteins are distantly related to the α -subunit of the heterotrimeric G proteins discussed earlier in this chapter.

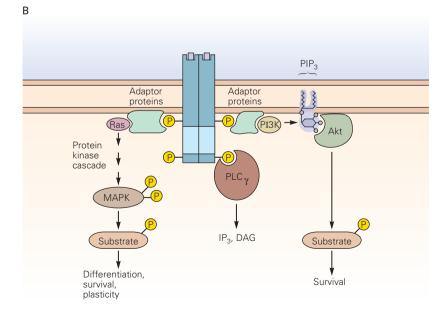

Ras becomes active following the exchange of a bound molecule of GDP for GTP, similar to the activation

Figure 11–9 Receptor tyrosine kinases are a major class of metabotropic receptors.

A. Receptor tyrosine kinases are monomers in the absence of a ligand. The receptor contains a large extracellular binding domain that is connected by a single transmembrane segment to a large intracellular region that contains a catalytic tyrosine kinase domain. Ligand binding to the receptor often causes two receptor subunits to form dimers, enabling the enzyme to phosphorylate itself on various tyrosine residues on the cytoplasmic side of the membrane.

B. After the receptor is autophosphorylated, several downstream signaling cascades become activated through the binding of specific adaptor proteins to the receptor phosphotyrosine residues (P). The signaling cascade on the left illustrates the activation of mitogen-activated protein kinase (MAPK). A series of adaptor proteins recruits the small guanosine triphosphate (GTP)-binding protein Ras, which activates a protein kinase cascade, leading to the dual phosphorylation of MAP kinase on nearby threonine and tyrosine residues. The activated MAP kinase then phosphorylates substrate proteins on serine and threonine residues, including ion channels and transcription factors. Signaling pathways on the right illustrate the activation of the Akt protein kinase (also called PKB). Adaptor proteins first activate phosphoinositide 3-kinase (PI3K), which adds a phosphate group to PIP2, yielding PIP3, which then enables Akt activation. In yet another pathway, phospholipase Cy becomes activated on binding to a different phosphotyrosine residue, providing a mechanism for producing inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG) that does not rely on G proteins. (PLCγ, phospholipase Cγ.)

of trimeric G proteins. The activated Ras protein then initiates a cascade of reactions involving two upstream kinase kinases that lead to the phosphorylation and activation of MAP kinase. Activated MAP kinases have several important actions. They translocate to the nucleus where they turn on gene transcription by phosphorylating certain transcription factors. This action is thought to be important in stabilizing long-term memory formation. MAP kinases also phosphorylate cytoplasmic and membrane proteins to produce short-term modulatory actions (Figure 11–9).

The Physiological Actions of Ionotropic and Metabotropic Receptors Differ

Second-Messenger Cascades Can Increase or Decrease the Opening of Many Types of Ion Channels

The structural differences between metabotropic and ionotropic receptors are reflected in their functional effects (Table 11–1). Metabotropic receptor actions are much slower than ionotropic ones. The physiological action of the two classes of receptors also differs.

Ionotropic receptors regulate channels that function as simple on-off switches, those whose main job is either to excite a neuron to fire an action potential or to inhibit the neuron from firing. Because these channels are normally confined to the postsynaptic region of the membrane, the action of ionotropic receptors is local. Conversely, metabotropic receptors, because they activate diffusible second messengers, can act on channels some distance from the receptor. As a result, metabotropic receptors regulate a variety of channel types, including resting channels, voltage-gated channels that generate the action potential or provide Ca²⁺ influx for neurotransmitter release, and ligand-gated channels.

Finally, whereas transmitter binding always leads to an increase in the opening of ionotropic receptor-channels, the activation of metabotropic receptors can lead to either an increase or a decrease in channel opening. For example, MAP kinase phosphorylation of an inactivating (A-type) K⁺ channel in the dendrites of hippocampal pyramidal neurons decreases the K⁺ current magnitude, thereby enhancing dendritic action potential firing.

The slow synaptic actions of metabotropic receptors normally are insufficient to cause a cell to fire an action potential. But they can greatly influence electrophysiological properties of a neuron. By acting on resting and voltage-gated channels in the neuron's cell body and dendrites, metabotropic receptor actions can alter resting potential, input resistance, length and time constants, threshold potential, action potential duration, and repetitive firing characteristics. By acting on channels in axon terminals and the postsynaptic membrane, metabotropic receptors can also modulate, respectively, neurotransmitter release and the opening of ionotropic receptor-channels, thereby regulating synaptic transmission. These various actions of metabotropic receptors are referred to as *modulatory synaptic actions* (Figure 11–10).

The distinction between direct and indirect regulation of ion channels is nicely illustrated by cholinergic synaptic transmission in autonomic ganglia. Stimulation of the presynaptic nerve releases ACh from the nerve terminals. This directly opens nicotinic ACh receptor-channels, producing a fast EPSP in the post-synaptic neuron. The fast EPSP is followed by a slow EPSP that takes approximately 100 ms to develop but which then lasts for several seconds. The slow EPSP is produced by the activation of metabotropic muscarinic ACh receptors that close a delayed-rectifier K⁺ channel called the muscarine-sensitive (or M-type) K⁺ channel. These voltage-gated channels are partially activated

	Ion channels involved	Effect on total membrane conductance	Contribution to action potential	Time course	Second messenger	Nature of synaptic action
EPSP caused by opening of channels	Non selective cation channel	Increase	Triggers action potential	Usually fast (milliseconds)	None	Mediating
EPSP caused by closing of channels	K ⁺ channel	Decrease	Modulates action potential	Slow (seconds or minutes)	Cyclic AMP (or other second messengers)	Modulating

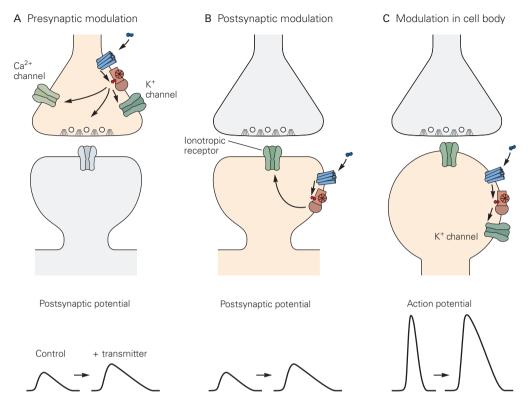

Figure 11–10 The modulatory actions of second messengers can occur at three cellular sites.

A. In the presynaptic neuron second messengers can modulate the activity of K^+ and Ca^{2+} channels, as well as the transmitter release machinery, to regulate the efficacy of transmitter release and thus the size of the fast postsynaptic potential mediated by ionotropic receptors.

B. In the postsynaptic neuron second messengers can alter directly the amplitude of postsynaptic potentials by modulating ionotropic receptors.

C. Second messengers can also affect the function of resting and voltage-gated channels in the soma and dendrites, thus altering a variety of electrical properties of the cell, including resting potential, input resistance, length and time constants, threshold, and action potential duration (as illustrated here).

when the cell is at rest, and the current through them helps determine the cell resting potential and input resistance (Figure 11–11).

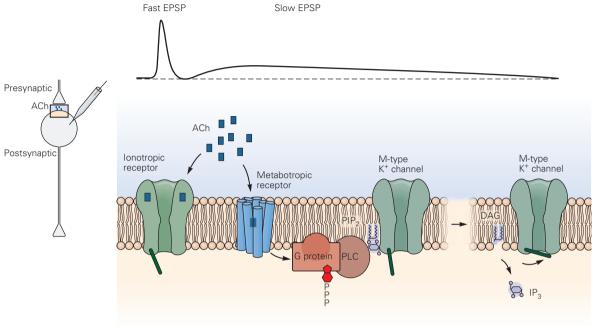

The M-type K⁺ channel is distinguished from other delayed-rectifier K⁺ channels by its slow activation. It requires several hundred milliseconds to fully activate on depolarization. Closure of the M-type channels in response to muscarinic stimulation causes a decrease in K⁺ efflux from the cell at the resting potential. As a result, K⁺ efflux no longer balances the Na⁺ influx through resting channels, and the net influx of Na⁺ leads to membrane depolarization (Figure 11–11).

How far will the membrane depolarize? Membrane depolarization decreases the inward driving force on Na^+ and increases the outward driving force on K^+ , such that the net inward current decreases. Thus the membrane will depolarize until the decrease in K^+

conductance (resulting from the closure of the M-type channels) is offset by the increase in the outward driving force on K⁺ and the decrease in the inward driving force on Na⁺ (as a result of the depolarization). At this new steady-state membrane potential the outward K⁺ current and inward Na⁺ current are again in balance.

Although the magnitude of the slow EPSP caused by closure of the M-type K⁺ channels is relatively modest, the decrease in K⁺ conductance profoundly increases action potential firing in response to a fast excitatory input. What are the special properties of the slow EPSP that produce this effect? First, the depolarization resulting from the reduction in resting K⁺ conductance drives the membrane closer to threshold. Second, the increase in input resistance decreases the amount of excitatory current necessary to depolarize the cell by a given voltage. Third, the reduction in the

A Fast and slow synaptic transmission

B The effect of muscarine on the M-type K+ current

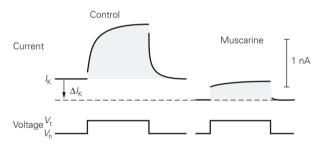

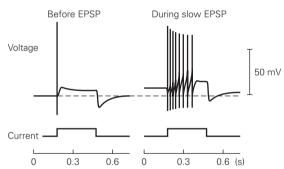

Figure 11–11 Fast ionotropic and slow metabotropic synaptic actions at autonomic ganglia.

A. The release of ACh onto a postsynaptic neuron in autonomic ganglia produces a fast excitatory postsynaptic potential (EPSP) followed by a slow EPSP. The fast EPSP is produced by activation of ionotropic nicotinic ACh receptors. The slow EPSP is produced by activation of metabotropic muscarinic ACh receptors. This receptor stimulates PLC to hydrolyze PIP $_2$, yielding IP $_3$ and DAG. The decrease in PIP $_2$ causes the closure of the M-type delayed-rectifier K+ channel.

B. Voltage clamp recordings indicate that ACh decreases the magnitude of the current carried by the M-type K+ channel. The depolarization of the membrane from a negative holding potential ($V_{\rm h}$, typically –60 mV) to a more positive test potential ($V_{\rm t}$, typically –30 mV) normally causes a slow increase in outward K+ current ($I_{\rm k}$) as the M-type K+ channels activate (control). Application of muscarine, a plant alkaloid that selectively

C The anti-accommodation effect of M-type K⁺ current inhibition

stimulates the muscarinic ACh receptor, decreases the outward K^+ current at the holding potential (note the shift in base line current, ΔI_{κ}) by closing the M-type K^+ channels that are open at rest. The functional loss of M-type channels also decreases the magnitude of the slowly activated K^+ current in response to the step depolarization. (Adapted, with permission, from Adams et al. 1986.)

C. In the absence of muscarinic ACh receptor stimulation, the neuron fires only a single action potential in response to a prolonged depolarizing current stimulus, a process termed accommodation (left). This is because the slow activation of the M-type K+ channel repolarizes the membrane below threshold. When the same current stimulus is applied during a slow EPSP, the neuron fires a more sustained train of action potentials (right) because the decrease in M-type current decreases the extent to which the membrane repolarizes during the stimulus. (Adapted, with permission, from Adams et al. 1986.)

delayed K⁺ current enables the cell to produce a more sustained firing of action potentials in response to a prolonged depolarizing stimulus.

In the absence of ACh, a ganglionic neuron normally fires only one or two action potentials and then stops firing in response to prolonged excitatory stimulation that is just above threshold. This process, termed *accommodation*, results in part from the increase in M-type K⁺ current in response to the prolonged depolarization, which helps repolarize the membrane below threshold. As a result, if the same prolonged stimulus is applied during a slow EPSP (when the M-type K⁺ channels are closed), the neuron remains depolarized above threshold during the entire stimulus and thus fires a prolonged burst of impulses, a process termed *anti-accommodation* (Figure 11–11C). As this modulation by ACh illustrates, the M-type K⁺ channels do more than help set the resting potential—they also control excitability.

AG protein mediates the modulation of the M-type channel by muscarinic receptor activation. However, until recently the target effector of the G protein remained a mystery. Although a number of lines of evidence implicated the PIP, hydrolysis pathway, neither PKC nor IP₃ seemed to play a role in regulating M-type channel opening. It is now known that PIP, is a necessary cofactor required for the proper function of many types of channels, including the M-type channels. As a result, stimulation of muscarinic ACh receptors that activate phospholipase C leads to closure of the M-type channels because of the decrease in PIP, levels in the membrane. Thus, M-type channels are regulated by the degradation of a substance rather than the synthesis of a chemical messenger. How PIP, binding enables proper functioning of the M-type channels remains unknown.

Although we do not know precisely the molecular mechanisms regulating M-type channels, we do have a more detailed understanding of how effectors in other types of modulatory actions regulate channel function. We shall first describe the simplest mechanism, the direct gating of ion channels by G proteins, and then consider a more complex mechanism dependent on protein phosphorylation by PKA.

G Proteins Can Modulate Ion Channels Directly

The simplest mechanism for activating an ion channel is direct gating of an ionotropic receptor-channel, as when ACh binds and opens the nicotinic ACh receptor-channel. The simplest mechanism for the indirect gating of a channel is when a metabotropic receptor releases a G protein subunit that directly interacts with the channel to modify its opening. This mechanism is used to gate two kinds of ion channels: the G

protein-gated inward-rectifier K⁺ channel (GIRK) and a voltage-dependent Ca^{2+} channel. With both kinds of channels, the G protein's $\beta\gamma$ complex is the mediator (Figure 11–12A).

The GIRK channel, like other inward-rectifier channels, passes current more readily in the inward than the outward direction, although in physiological situations K⁺ current is always outward. As we learned in Chapter 5, inward-rectifier channels resemble a truncated voltagegated K⁺ channel in having two transmembrane regions connected by a P-region loop that forms the selectivity filter in the channel (see Figure 5–12).

In the 1920s Otto Loewi described how the release of ACh in response to stimulation of the vagus nerve slows the heart rate (Figure 11-12B). We now know that the ACh activates muscarinic receptors to stimulate G protein activity, which directly opens the GIRK channel. For many years this transmitter action was puzzling because it has properties of both ionotropic and metabotropic receptor actions. The time course of activation of the K⁺ current following release of ACh is slower (50 to 100 ms rise time) than that of ionotropic receptors (submillisecond rise time). However, the rate of K+ channel activation is much faster than that of second-messenger-mediated actions that depend on protein phosphorylation (which can take many seconds to turn on). Although biochemical and electrophysiological studies clearly demonstrated that a G protein was required for this action, patch-clamp experiments showed that the G protein did not trigger production of a diffusible second messenger (Figure 11-12C). These findings were reconciled when it was found that activation of the muscarinic receptors releases the G protein's $\beta \gamma$ -subunits, which directly open the K⁺ channel.

Activation of GIRK channels hyperpolarizes the membrane in the direction of $E_{\rm K}$ (–80 mV). In certain classes of spontaneously active neurons the outward K⁺ current through these channels acts predominantly to decrease the neuron's intrinsic firing rate, opposing the slow depolarization caused by excitatory pacemaker currents carried by the hyperpolarization-activated, cyclic nucleotide-regulated (HCN) channels (see Chapter 7). Because GIRK channels are activated by neurotransmitters, they provide a means for regulating the firing rate of excitable cells. These channels are regulated in a wide variety of neurons by a large number of transmitters and neuropeptides that act on different G protein-coupled receptors to activate either $G_{\rm i}$ or $G_{\rm o}$, thereby releasing $\beta_{\rm v}$ subunits.

Several G protein-coupled receptors also act to inhibit the opening of certain voltage-gated Ca^{2+} channels, again as a result of the direct binding to the channel of the $\beta\gamma$ complex of G_i or G_o . Because Ca^{2+}

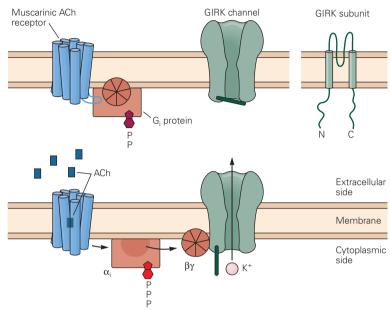

Figure 11–12 Some G proteins open ion channels directly without employing second messengers.

A. An inward-rectifying K⁺ channel (GIRK) is opened directly by a G protein. Binding of ACh to a muscarinic receptor causes the dissociation of the G_i protein $\alpha_i \beta \gamma$ -complex; the free $\beta \gamma$ -subunits bind to a cytoplasmic domain of the channel, causing the channel to open.

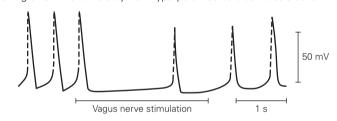

B. Stimulation of the parasympathetic vagus nerve releases ACh, which acts at muscarinic receptors to open GIRK channels in cardiac muscle cell membranes. The current through the GIRK channel hyperpolarizes the cells, thus helping to slow the heart rate. (Adapted, with permission, from Toda and West 1967.)

C. Three single-channel records show that opening of GIRK channels does not involve a freely diffusible second messenger. In this experiment the pipette contained a high concentration of K+, which makes E_{κ} less negative. As a result, when GIRK channels open, they generate brief pulses of inward (downward) current. In the absence of ACh, channels open briefly and infrequently (top record). Application of ACh in the bath (outside the pipette) does not increase channel opening in the patch of membrane under the pipette (middle record). The ACh must be in the pipette to activate the channel (bottom record). This is because the free $\beta\gamma$ -subunits, released by the binding of ACh to its receptor, remain tethered to the membrane near the receptor and can only activate nearby channels. The subunits are not free to diffuse to the channels under the patch pipette. (Reproduced, with permission, from Soejima and Noma 1984.)

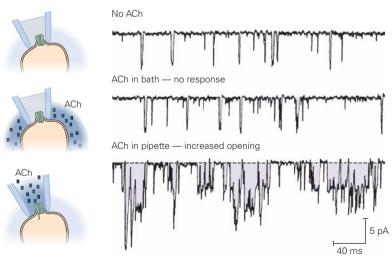

A Direct opening of the GIRK channel by a G protein

B Opening of GIRK channels by ACh hyperpolarizes cardiac muscle cells

C Opening of GIRK channels by ACh does not require second messengers

influx through voltage-gated Ca^{2+} channels normally has a depolarizing effect, the dual action of G protein $\beta\gamma$ -subunits— Ca^{2+} channel inhibition and K+ channel activation—strongly inhibits neuronal firing. As we will see in Chapter 12, inhibition of voltage-gated Ca^{2+} channels in presynaptic terminals through G protein $\beta\gamma$ -subunits can suppress the release of neurotransmitter, a process termed *presynaptic inhibition*.

Cyclic AMP-Dependent Protein Phosphorylation Can Close Potassium Channels

In the marine mollusk *Aplysia*, stimulation of certain interneurons results in the release of the transmitter serotonin. This produces a slow EPSP in a group of mechanoreceptor sensory neurons. These sensory neurons initiate defensive withdrawal reflexes in response to tactile stimuli through fast, excitatory synapses with motor neurons. Serotonin sensitizes this reflex, enhancing the animal's response to a stimulus, resulting in a simple form of learning (see Chapter 66).

The modulatory action of serotonin depends on its binding to a G protein-coupled receptor that activates a G_s protein, which elevates cAMP and thus activates PKA. This leads to the direct phosphorylation and subsequent closure of the serotonin-sensitive (or S-type) K^+ channel that acts as a resting channel (Figure 11–13). Like the closing of the M-type K^+ channel with ACh, closure of the S-type K^+ channel decreases K^+ efflux from the cell, thereby depolarizing the cell and decreasing its resting membrane conductance.

The opening of the same S-type channels can be enhanced by the neuropeptide FMRFamide, acting through 12-lipoxygenase metabolites of arachidonic acid. This enhanced K+ channel opening leads to a slow hyperpolarizing IPSP associated with an increase in resting membrane conductance. Thus a single channel can be regulated in opposing ways by distinct second-messenger pathways that produce opposing effects on neuronal excitability. A resting K+ channel with two pore-forming domains in each subunit (TREK) in mammalian neurons is also dually regulated by PKA and arachidonic acid in a manner very similar to the dual regulation of the S-type channel in *Aplysia*.

Synaptic Actions Mediated by Phosphorylation Are Terminated by Phosphoprotein Phosphatases

Synaptic actions mediated by phosphorylation are terminated by phosphoprotein phosphatases, enzymes that remove phosphoryl groups from proteins, thereby generating inorganic phosphate. One class of phosphatases dephosphorylates proteins at serine or threonine residues

and hence can reverse the actions of PKA, PKC, and Ca²⁺/calmodulin kinase (Figure 11–14). A second class dephosphorylates proteins at tyrosine residues. Finally, a third group is specific for the pair of adjacent phosphorylated residues that mediate activation of MAP kinases.

Phosphatase activity can be regulated by different mechanisms. One of the major serine-threonine phosphatases in neurons, phosphatase-1, is under the control of a regulatory protein called inhibitor-1. Inhibitor-1 binds to and inhibits phosphatase-1 only after the inhibitor has itself been phosphorylated by PKA (Figure 11–14). An increase in cAMP therefore has two effects that enhance levels of protein phosphorylation: It increases the rate of phosphorylation by activating PKA and decreases the rate of dephosphorylation by inhibiting phosphatase-1.

Another serine-threonine phosphatase, calcineurin, is activated in response to an increase in the concentration of Ca²⁺ inside a cell. The Ca²⁺ binds to calmodulin and the Ca2+/calmodulin complex then activates the phosphatase. One of the important functions of calcineurin is to dephosphorylate inhibitor-1. In neurons of the basal ganglia, Paul Greengard and colleagues showed that dopamine (acting through metabotropic D₁ receptors and cAMP production) activates PKA, which in turn phosphorylates inhibitor-1 (called DARPP-32 in these cells). The resulting inhibition of phosphatase-1 leads to an overall enhancement of phosphorylation in the neuron. However, if NMDA receptors are activated by release of glutamate, the resultant Ca2+ influx can stimulate calcineurin. This leads to the dephosphorylation of inhibitor-1, which relieves the inhibition of phosphatase-1, resulting in a decrease in overall levels of phosphorylation in the basal ganglion neurons. As we shall learn later in Chapter 67, a similar calcineurin cascade is thought to underlie a long-lasting depression of synaptic transmission in the hippocampus.

Second Messengers Can Endow Synaptic Transmission with Long-Lasting Consequences

So far we have described how synaptic second messengers alter the biochemistry of neurons for periods of time lasting seconds to minutes. Second messengers can also effect long-term changes lasting days to weeks as a result of alterations in a cell's expression of specific genes (Figure 11–15). Such changes in gene expression result from the ability of second-messenger cascades to control the activity of transcription factors, regulatory proteins that control mRNA synthesis.

The activity of some transcription factors can be directly regulated by phosphorylation. For example, a transcription factor termed the cAMP response element-binding protein (CREB) is activated when

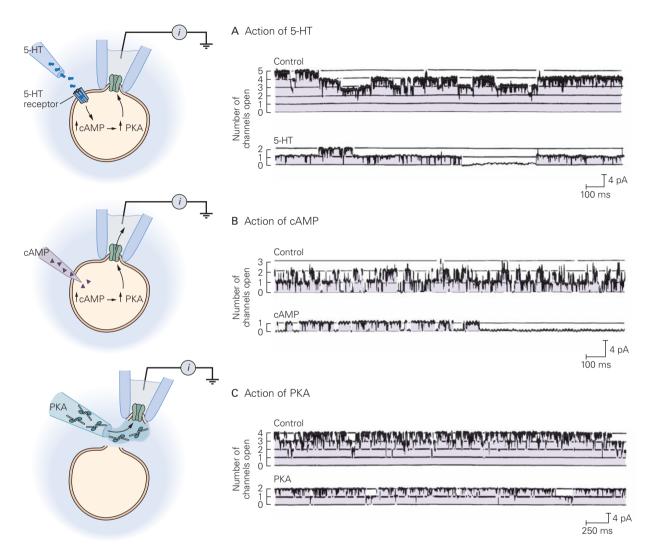

Figure 11–13 Serotonin closes a K+ channel through the diffusible second-messenger cAMP. Serotonin (5-HT) produces a slow excitatory postsynaptic potential (EPSP) in Aplysia sensory neurons by closing the serotonin-sensitive or S-type K+ channels. The 5-HT receptor is coupled to G_s , which stimulates adenylyl cyclase. The increase in cAMP activates cAMP-dependent protein kinase A (PKA), which phosphorylates the S-type channel, leading to its closure. Single-channel recordings illustrate the actions of 5-HT, cAMP, and PKA on the S-type channels.

A. Addition of 5-HT to the bath closes three of five S-type K⁺ channels active in this cell-attached patch of membrane. The experiment implicates a diffusible messenger, as the 5-HT applied in the bath has no direct access to the S-type channels in the membrane under the pipette. Each channel opening

contributes an outward (positive) current pulse. (Adapted, with permission, from Siegelbaum, Camardo, and Kandel 1982.)

- **B.** Injection of cAMP into a sensory neuron through a microelectrode closes all three active S-type channels in this patch. The bottom trace shows the closure of the final active channel in the presence of cAMP (Adapted, with permission, from Siegelbaum, Camardo, and Kandel 1982.)
- **C.** Application of the purified catalytic subunit of PKA to the cytoplasmic surface of the membrane closes two out of four active S-type K⁺ channels in this cell-free patch. ATP was added to the solution bathing the inside surface of the membrane to provide the source of phosphate for protein phosphorylation. (Adapted, with permission, from Shuster et al. 1985.)

phosphorylated by PKA, Ca²⁺/calmodulin-dependent protein kinases, PKC, or MAP kinases. Once activated, CREB enhances transcription by binding a component of the transcription machinery, the CREB-binding protein (CBP). CBP activates transcription by recruiting RNA polymerase II and by functioning as a histone acetylase, adding acetyl groups to certain histone lysine residues. The acetylation weakens the binding between histones and DNA, which opens up the chromatin structure and enables specific genes to be transcribed. The changes in transcription and chromatin structure are important for regulating neuronal development, as well as for long-term learning and memory (see Chapters 66 and 67).

An Overall View

Signaling between neurons occurs when neurotransmitters bind to their postsynaptic receptors. Two distinct

classes of receptors, ionotropic and metabotropic, differ widely in biochemical mechanism, duration of action, and physiological function.

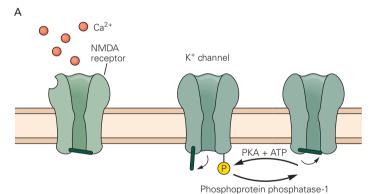

Binding of transmitter to an ionotropic receptor directly opens an ion channel that is part of the receptor macromolecule. These ligand-gated receptor-channels produce the fastest and briefest type of synaptic action, lasting only a few milliseconds. This fast synaptic transmission mediates most motor actions and sensory processing.

Longer-lasting effects of transmitters are mediated by two major types of metabotropic receptors: G protein-coupled receptors and receptor tyrosine kinases. G protein-coupled receptors are proteins with seven transmembrane segments. They are members of a large gene superfamily and all act through G proteins, either to activate second-messenger cascades or directly alter ion channel activity. Prominent second messengers are cAMP and the products of hydrolysis of phospholipids: IP₃, diacylglycerol, and arachidonic acid.

Figure 11–14 Phosphoprotein phosphatases end the actions of protein kinases.

A. The forward rate of phosphorylation of substrate proteins (here a K⁺ channel) is controlled by protein kinases, the reverse rate by phosphoprotein phosphatases.

B. The extent and duration of phosphorylation can be controlled by regulation of phosphatase activity through a protein called inhibitor-1. When inhibitor-1 is phosphorylated by cAMP-dependent protein kinase (PKA), it binds to and blocks the activity of phosphoprotein phosphatase-1. The extent of phosphorylation of inhibitor-1 is controlled by another phosphatase, calcineurin, which is activated by the Ca²⁺/calmodulin complex. In this manner Ca²⁺ entering the cell through the N-methyl-D-aspartate (NMDA)-type glutamate receptors activates calcineurin and triggers dephosphorylation of inhibitor-1. This in turn leads to the disinhibition of phosphoprotein phosphatase-1, which then dephosphorylates many substrates, including the K+ channel. (ATP, adenosine triphosphate; P, phosphate; Glu, glutamate.) (Adapted, with permission, from Halpain, Girault, and Greengard 1990.)

Inhibitor-1

Figure 11-15 A single neurotransmitter can have either short-term or long-term effects on an ion channel. In this example a short exposure to transmitter activates the cAMP second-messenger system (1), which in turn activates PKA (2). The kinase phosphorylates a K+ channel; this produces a synaptic potential that lasts for several minutes and modifies the excitability of the neuron (3). With sustained activation of the receptor, the kinase translocates to the nucleus, where it phosphorylates one or more transcription factors that turn on gene expression (4). As a result of the new protein synthesis, the synaptic actions are prolonged—closure of the channel and changes in neuronal excitability last days or longer (5). (Pol, polymerase.)

Many second-messenger actions involve phosphorylation of a variety of target proteins, including ion channels, thereby changing the functional state of the channels. These second-messenger actions generally last from seconds to minutes and thus do not mediate rapid behaviors. Rather they modulate the strength and efficacy of fast synaptic transmission—by modulating transmitter release or the responsiveness of ionotropic receptors to their ligand—or the electrical excitability of postsynaptic cells. Second-messenger actions not only open ion channels, as do the fast synaptic actions, but also close channels that are normally open in the absence of transmitter, thereby decreasing membrane conductance.

These modulatory actions are important in producing emotional states, mood, arousal, and simple forms of learning and memory. Many neurological and psychiatric disorders, including Parkinson disease, depression, anxiety, and schizophrenia, are thought to involve alterations in metabotropic receptor-dependent forms of synaptic transmission. Drugs that act to enhance or depress metabotropic receptor activation are important for treating these diseases.

The longest-lasting effects of neurotransmitters involve changes in gene expression, changes that can persist for days or longer. These more permanent actions are mediated by many of the same types of receptors and second-messenger pathways that operate in the

shorter-term modulatory actions of transmitters. The long-term processes, however, may require repeated stimulation of the receptors and more prolonged action of the second messengers. As we shall see in Chapters 66 and 67, synaptically induced changes in gene expression are critical for long-term memory storage.

An Overall View

Some of the Brain's most remarkable abilities, such as learning and memory, are thought to emerge from the elementary properties of chemical synapses, where presynaptic terminals release chemical transmitters that activate receptors in the membrane of the postsynaptic cell. In the last three chapters we saw how postsynaptic receptors control ion channels that generate the postsynaptic potential. Here we consider how electrical and biochemical events in the presynaptic terminal lead to the secretion of neurotransmitters. In the next chapter we examine the chemistry of the neurotransmitters themselves.

Transmitter Release Is Regulated by Depolarization of the Presynaptic Terminal

What are the signals at the presynaptic terminal that lead to the release of transmitter? Bernard Katz and Ricardo Miledi first demonstrated the importance of depolarization of the presynaptic membrane through the firing of a presynaptic action potential. For this purpose they used the giant synapse of the squid, a synapse large enough to permit insertion of electrodes into both pre- and postsynaptic structures. Two electrodes are inserted into the presynaptic terminal—one for stimulating and one for recording—and one electrode is inserted into the postsynaptic cell for recording the excitatory postsynaptic potential (EPSP), which provides an index of transmitter release (Figure 12–1A).

When the presynaptic neuron is stimulated it fires an action potential, and after a brief delay an EPSP large enough to trigger an action potential is recorded in the

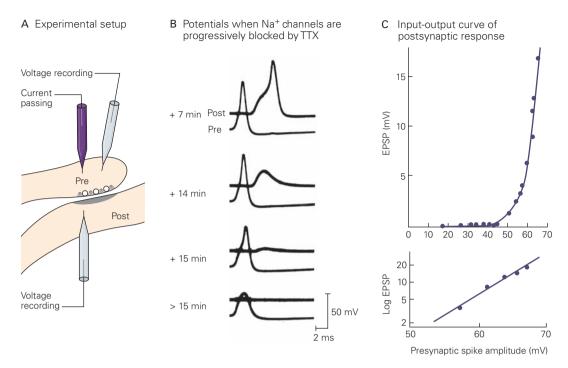

Figure 12–1 Transmitter release is triggered by changes in presynaptic membrane potential. (Adapted, with permission, from Katz and Miledi 1967a.)

A. Voltage recording electrodes are inserted in both the preand postsynaptic fibers of the giant synapse in the stellate ganglion of a squid. A current-passing electrode is also inserted presynaptically to elicit a presynaptic action potential.

B. Tetrodotoxin (TTX) is added to the solution bathing the cell to block the voltage-gated Na⁺ channels that underlie the action potential. The amplitudes of both the presynaptic action potential and the excitatory postsynaptic potential (EPSP) gradually decrease as more and more Na⁺ channels are blocked. After 7 min the presynaptic action potential can still produce a suprathreshold EPSP that triggers an action potential in the postsynaptic cell. After about 14 to 15 min the presynaptic spike gradually becomes smaller and produces smaller postsynaptic depolarizations. When the presynaptic spike is reduced to 40 mV or less, it fails to produce an EPSP. Thus the size of the

presynaptic depolarization (here provided by the action potential) controls the magnitude of transmitter release.

C. An input–output curve for transmitter release is determined from the dependence of the amplitude of the EPSP on the amplitude of the presynaptic action potential. This relation is obtained by stimulating the presynaptic nerve during the onset of the blockade by TTX of the presynaptic Na⁺ channels, when there is a progressive reduction in the amplitude of the presynaptic action potential and postsynaptic depolarization. The upper plot demonstrates that (1) a 40 mV presynaptic action potential is required to produce a postsynaptic potential. Beyond this threshold there is a steep increase in amplitude of the EPSP in response to small increases in the amplitude of the presynaptic potential and (2) the relationship between the presynaptic spike and the EPSP is logarithmic, as shown in the lower plot. A 10 mV increase in the presynaptic spike produces a 10-fold increase in the EPSP.

postsynaptic cell. Katz and Miledi then asked how the presynaptic action potential triggers transmitter release. They found that as voltage-gated Na⁺ channels are blocked by application of tetrodotoxin, successive action potentials become progressively smaller. As the action potential is reduced in size, the EPSP decreases accordingly (Figure 12–1B). When the Na⁺ channel blockade becomes so profound as to reduce the amplitude of the presynaptic spike below 40 mV (positive to the resting potential), the EPSP disappears altogether. Thus the amount of transmitter release (as

measured by the size of the postsynaptic depolarization) is a steep function of the amount of presynaptic depolarization (Figure 12–1C).

Katz and Miledi next investigated how presynaptic depolarization triggers transmitter release. The action potential is produced by an influx of Na⁺ and an efflux of K⁺ through voltage-gated channels. To determine whether Na⁺ influx or K⁺ efflux is required to trigger transmitter release, Katz and Miledi first blocked the Na⁺ channels with tetrodotoxin. They then asked whether direct depolarization of the presynaptic membrane,

by current injection, would still trigger transmitter release. Indeed, depolarization of the presynaptic membrane beyond a threshold of about 40 mV positive to the resting potential elicits an EPSP in the postsynaptic cell. Beyond that threshold, progressively greater depolarization leads to progressively greater amounts of transmitter release. This result shows that during a normal action potential presynaptic Na⁺ influx is not necessary for release. Rather Na⁺ influx is important only insofar as it depolarizes the membrane enough for transmitter release to occur (Figure 12–2B).

To examine the contribution of K^+ efflux to transmitter release, Katz and Miledi blocked the voltage-gated K^+ channels with tetraethylammonium at the same time they blocked the voltage-sensitive Na^+ channels with tetrodotoxin. They then injected a depolarizing current into the presynaptic terminals and found that

the EPSPs were of normal size, indicating that normal transmitter release occurred (Figure 12–2C). Thus neither Na⁺ nor K⁺ flux is required for transmitter release.

In the presence of tetraethylammonium the current pulse elicits a maintained presynaptic depolarization because the K⁺ current that normally repolarizes the presynaptic membrane is blocked. As a result, transmitter release is sustained throughout the current pulse as reflected in the prolonged depolarization of the postsynaptic cell. The sustained depolarization increased the accuracy of the measurements and permitted Katz and Miledi to determine a complete inputoutput curve relating presynaptic depolarization to transmitter release (Figure 12–2D). They confirmed the steep dependence of transmitter release on presynaptic depolarization. In the range of depolarization over which transmitter release increases (40–70 mV positive

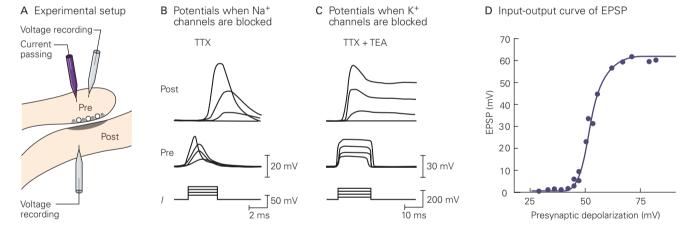

Figure 12–2 Transmitter release is not directly triggered by the opening of presynaptic voltage-gated Na⁺ or K⁺ channels. (Adapted, with permission, from Katz and Miledi 1967a.)

A. Voltage recording electrodes are inserted in both the preand postsynaptic fibers of the giant synapse in the stellate ganglion of a squid. A current-passing electrode has also been inserted into the presynaptic cell.

B. Depolarizing the presynaptic terminal with direct current injection through a microelectrode can trigger transmitter release even after the voltage-gated Na⁺ channels are completely blocked by adding tetrodotoxin (TTX) to the cell-bathing solution. Three sets of traces represent (from bottom to top) the depolarizing current pulse injected into the presynaptic terminal (*I*), the resulting potential in the presynaptic terminal (**Pre**), and the EPSP generated by the release of transmitter onto the postsynaptic cell (**Post**). Progressively stronger current pulses in the presynaptic cell produce correspondingly greater depolarizations of the presynaptic terminal. The greater the presynaptic depolarization, the larger the EPSP. The presynaptic depolarizations are not maintained throughout the duration

of the depolarizing current pulse because delayed activation of the voltage-gated $\mathsf{K}^{\scriptscriptstyle{+}}$ channels causes repolarization.

C. Transmitter release occurs even after the voltage-gated Na⁺ channels have been blocked with TTX and the voltage-gated K⁺ channels have been blocked with tetraethylammonium (TEA). In this experiment TEA was injected into the presynaptic terminal. The three sets of traces represent the same measurements as in part B. Because the presynaptic K⁺ channels are blocked, the presynaptic depolarization is maintained throughout the current pulse. The large sustained presynaptic depolarization produces large sustained EPSPs.

D. Blocking both the Na $^+$ and K $^+$ channels permits accurate control of presynaptic voltage and the determination of a complete input–output curve. Beyond a certain threshold (40 mV positive to the resting potential) there is a steep relationship between presynaptic depolarization and transmitter release, as measured from the size of the EPSP. Depolarizations greater than a certain level do not cause any additional release of transmitter. The initial presynaptic resting membrane potential was approximately -70 mV.

to the resting level) a 10 mV increase in depolarization produces a 10-fold increase in transmitter release. Depolarization of the presynaptic membrane above an upper limit produces no further increase in the postsynaptic potential.

Release Is Triggered by Calcium Influx

Katz and Miledi next turned their attention to Ca²⁺ ions. Earlier, Katz and José del Castillo had found that increasing the extracellular Ca²⁺ concentration enhanced transmitter release, whereas lowering the concentration reduced and ultimately blocked synaptic transmission. Because transmitter release is an intracellular process, these findings implied that Ca²⁺ must enter the cell to influence transmitter release.

Previous work on the squid giant axon membrane had identified a class of voltage-gated Ca²⁺ channels, the opening of which results in a large Ca²⁺ influx because of the large inward electrochemical driving force on Ca²⁺. The extracellular Ca²⁺ concentration, approximately 2 mM in vertebrates, is normally four orders of magnitude greater than the intracellular concentration, approximately 10⁻⁷ M at rest. However, because these Ca²⁺ channels are sparsely distributed along the axon they cannot, by themselves, provide enough current to produce a regenerative action potential.

Katz and Miledi found that the Ca²⁺ channels were much more abundant at the presynaptic terminal. There, in the presence of tetraethylammonium and tetrodotoxin, a depolarizing current pulse was sometimes able to trigger a regenerative depolarization that required extracellular calcium, a calcium spike. Katz and Miledi therefore proposed that Ca²⁺ serves dual functions. It is a carrier of depolarizing charge during the action potential (like Na⁺), and it is a special chemical signal—a second messenger—conveying information about changes in membrane potential to the intracellular machinery responsible for transmitter release. Calcium ions are able to serve as an efficient chemical signal because of their low resting concentration, approximately 10⁵ fold lower than the resting concentration of Na⁺. As a result, the small amounts of ions that enter or leave a cell during an action potential can lead to large percentage changes in intracellular Ca²⁺ that can trigger various biochemical reactions. Proof of the importance of Ca²⁺ channels in release has come from more recent experiments showing that specific toxins that block Ca²⁺ channels also block release.

The properties of the voltage-gated Ca²⁺ channels at the squid presynaptic terminal were measured by Rodolfo Llinás and his colleagues. Using a voltage

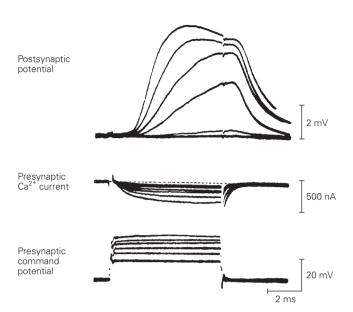

Figure 12–3 Transmitter release is regulated by Ca²⁺ influx into the presynaptic terminals through voltage-gated Ca²⁺ channels. The voltage-sensitive Na⁺ and K⁺ channels in a squid giant synapse were blocked by tetrodotoxin and tetraethylammonium. The membrane of the presynaptic terminal was voltage-clamped and membrane potential stepped to six different command levels of depolarization (bottom). The amplitude of the postsynaptic depolarization (top) varies with the size of the presynaptic inward Ca²⁺ current (middle) because the amount of transmitter release is a function of the concentration of Ca²⁺ in the presynaptic terminal. The notch in the postsynaptic potential trace is an artifact that results from turning off the presynaptic command potential. (Adapted, with permission, from Llinás and Heuser 1977.)

clamp, Llinás depolarized the terminal while blocking the voltage-gated Na⁺ channels with tetrodotoxin and the K⁺ channels with tetraethylammonium. He found that graded depolarizations activated a graded inward Ca²⁺ current, which in turn resulted in graded release of transmitter (Figure 12–3). The Ca²⁺ current is graded because the Ca²⁺ channels are voltage-dependent like the voltage-gated Na⁺ and K⁺ channels. Calcium ion channels in squid terminals differ from Na⁺ channels, however, in that they do not inactivate quickly but stay open as long as the presynaptic depolarization lasts.

Calcium ion channels are concentrated in presynaptic terminals at *active zones*, the sites where neurotransmitter is released, exactly opposite the post-synaptic receptors (Figure 12–4). Calcium ions do not diffuse long distances from their site of entry because free Ca²⁺ ions are rapidly buffered by calcium-binding proteins. As a result, Ca²⁺ influx creates a sharp local

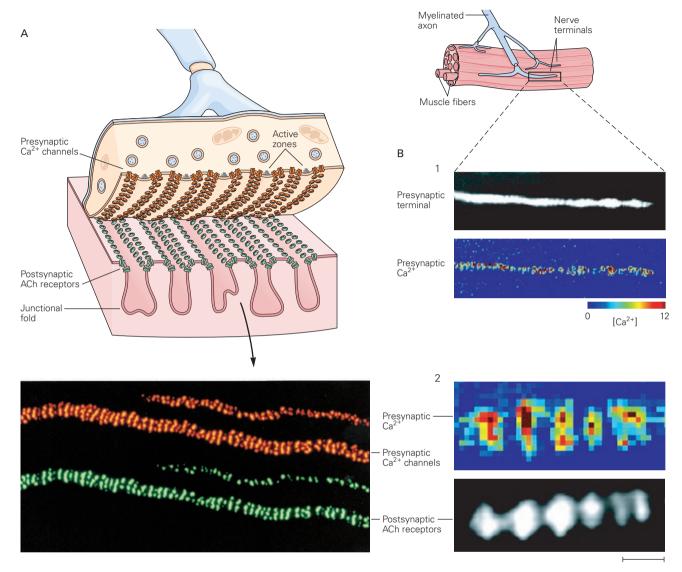

Figure 12–4 Calcium flowing into the presynaptic nerve terminal during synaptic transmission at the neuromuscular junction is concentrated at the active zone. Calcium channels in presynaptic terminals at the end-plate are concentrated opposite clusters of nicotinic acetylcholine (ACh) receptors on the postsynaptic muscle membrane. Two drawings show the frog neuromuscular junction.

A. The enlarged view shows the microanatomy of the neuromuscular junction with the presynaptic terminal peeled back. A fluorescent image shows the presynaptic Ca^{2+} channels (labeled with a Texas red-coupled marine snail toxin that binds to Ca^{2+} channels), and postsynaptic ACh receptors (labeled with fluorescently tagged α -bungarotoxin, which binds selectively to ACh receptors). The two images are normally superimposed but have been separated for clarity. The patterns of labeling with both probes are in almost precise register, indicating that the active zone of the presynaptic neuron is in almost perfect alignment with the postsynaptic membrane containing the high concentration of ACh receptors. (Reproduced, with permission, from Robitaille, Adler, and Charlton 1990.)

B. Calcium influx in presynaptic terminals is localized at active zones. Calcium can be visualized using calcium-sensitive fluorescent dyes. 1. A presynaptic terminal at a neuromuscular junction filled with the dye fura-2 under resting conditions is shown in the black and white image. The fluorescence intensity of the dye changes as it binds Ca²⁺. In the color image, colorcoded fluorescence intensity changes show local hot-spots of intracellular Ca²⁺ in response to a single presynaptic action potential. Red indicates regions with a large increase in Ca²⁺; blue indicates regions with little increase in Ca2+. Regular peaks of Ca2+ are seen along the terminal, corresponding to the localization of Ca²⁺ channels at the active zones. 2. The color image shows a high-magnification view of the peak increase in terminal Ca²⁺ levels. The corresponding black-and-white image shows fluorescence labeling of nicotinic ACh receptors in the postsynaptic membrane, illustrating the close spatial correspondence between areas of presynaptic Ca2+ influx and areas of postsynaptic receptors. The scale bar represents 2 µm. (Reproduced, with permission, from Wachman et al. 2004.)

rise in Ca²⁺ concentration at the active zones. This rise in Ca²⁺ in the presynaptic terminals can be visualized using Ca²⁺-sensitive fluorescent dyes (Figure 12–4B). One striking feature of transmitter release at all synapses is its steep and nonlinear dependence on Ca²⁺ influx; a twofold increase in Ca²⁺ influx can increase the amount of transmitter released by 16-fold. This relationship indicates that at some site, the *calcium sensor*, the cooperative binding of several Ca²⁺ ions is required to trigger release.

The Relation Between Presynaptic Calcium Concentration and Release

How much Ca²⁺ is necessary to induce release of neurotransmitters? To address this question Bert Sakmann and Erwin Neher and their colleagues measured synaptic transmission in the calyx of Held, a large synapse in the mammalian brain stem that is part of the auditory pathway. This synapse is specialized for very rapid and reliable transmission to allow for precise localization of sound in the environment.

The calyx forms a cup-like presynaptic terminal that engulfs a postsynaptic cell body (Figure 12–5A). To ensure that every action potential results in reliable synaptic transmission, the calyx synapse includes almost a thousand active zones that function as independent synapses. In contrast, synaptic terminals of a typical neuron in the brain contain only a single active zone. Because the calyx terminal is large, it is possible to insert electrodes into both the pre- and postsynaptic structures, much as with the squid giant synapse, and directly measure the synaptic coupling between the two compartments. This paired recording allows a precise determination of the time course of activity in the presynaptic and postsynaptic cells (Figure 12–5B).

These recordings revealed a brief lag of 1 to 2 ms between the onset of the presynaptic action potential and the postsynaptic excitatory synaptic potential, which accounts for what Sherrington termed the *synaptic delay*. Because Ca²⁺ channels open more slowly than Na⁺ channels, Ca²⁺ does not begin to enter the presynaptic terminal until the membrane has begun to repolarize. Surprisingly, once Ca²⁺ enters the terminal, transmitter is rapidly released with a delay of only a few hundred microseconds. Thus the synaptic delay is largely attributable to the time required to open Ca²⁺ channels. The astonishing speed of Ca²⁺ action indicates that, prior to Ca²⁺ influx, the biochemical machinery underlying the release process must already exist in a primed and ready state.

A presynaptic action potential normally produces only a brief rise in presynaptic Ca²⁺ concentration

because the Ca^{2+} channels open only for a short time. In addition, Ca^{2+} influx is localized at the active zone. These two properties contribute to a concentrated local pulse of Ca^{2+} that induces a burst of transmitter release (Figure 12–5B). As we shall see later in this chapter, the duration of the action potential regulates the amount of Ca^{2+} that flows into the terminal and thus the amount of transmitter release.

To determine how much Ca²⁺ is needed to trigger release, the Neher and Sakmann groups introduced into the presynaptic terminal an inactive form of Ca²⁺ that was complexed within a light-sensitive chemical cage. They also loaded the terminals with a fluorescent dye that alters its fluorescence upon binding Ca²⁺ and so can be used to assay the intracellular Ca²⁺ concentration. By uncaging the Ca2+ ions with a flash of light they could trigger transmitter release through a uniform, known increase in Ca²⁺ concentration. These experiments revealed that a rise in Ca2+ concentration of less than 1 µM is sufficient to induce release of some transmitter, but approximately 10 to 30 μ M Ca²⁺ is required to release the amount normally observed during an action potential. Here again the relationship between Ca²⁺ concentration and transmitter release is highly nonlinear, consistent with a model in which four or five Ca²⁺ ions must bind to the Ca²⁺ sensor to trigger release (Figure 12–5C,D).

Several Classes of Calcium Channels Mediate Transmitter Release

Calcium channels are found in all nerve cells and in many non-neuronal cells. In skeletal and cardiac muscle cells Ca²⁺ channels are important for excitation-contraction coupling; in endocrine cells they mediate release of hormones. Neurons contain five classes of voltage-gated Ca²⁺ channels: the L-type, P/Q-type, N-type, R-type, and T-type, each encoded by distinct genes or gene families. Each type has specific biophysical and pharmacological properties and physiological functions (Table 12–1).

Calcium channels are multimeric proteins whose distinct properties are determined by their pore-forming subunit, the α_1 -subunit. The α_1 -subunit is homologous to the α -subunit of the voltage-gated Na $^+$ channel, comprised of four repeats of a domain with six membrane-spanning segments that includes the S4 voltage-sensor and pore-lining P region (see Figure 7–14). Calcium channels also have auxiliary subunits (termed α_2 , β , γ , and δ) that modify the properties of the channel formed by the α_1 -subunit.

Four of the voltage-gated Ca²⁺ channels—the L-type, P/Q-type, N-type, and R-type—require fairly strong

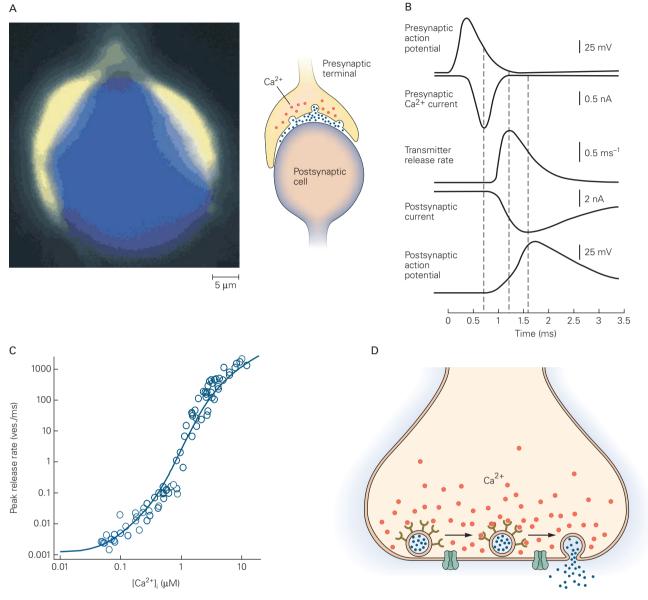

Figure 12–5 The precise relation between presynaptic Ca²⁺ and transmitter release at a central synapse has been measured. (Reproduced, with permission, from Meinrenken, Borst, and Sakmann 2003, and Sun et al. 2007.)

A. The large presynaptic terminal of the calyx of Held in the mammalian brain stem (yellow) engulfs a postsynaptic cell body (blue). Fluorescence image on left shows a calyx filled with a calcium-sensitive dye.

B. Time courses of the presynaptic action potential, presynaptic Ca²⁺ current, transmitter release rate, postsynaptic current through glutamate receptors, and the postsynaptic action potential. The **dashed lines** indicate the timing of the peak responses for the Ca²⁺ current, transmitter release, and postsynaptic action potential.

C. Transmitter release is steeply dependent on the Ca²⁺ concentration in the presynaptic terminal. The calyx was loaded with a caged Ca²⁺ compound that releases its bound Ca²⁺ in response

to a flash of ultraviolet light, and with a Ca^{2+} sensitive dye that allows measuring how much Ca^{2+} is released. By controlling the intensity of light one can regulate the increase in Ca^{2+} in the presynaptic terminal. The plot, on a logarithmic scale, shows the relation between the rate of vesicle release and intracellular Ca^{2+} concentration. The circles depict measurements from individual experiments, and the blue line depicts a fit of the data by a model that assumes that release is triggered by a major Ca^{2+} sensor that binds five Ca^{2+} ions, resulting in a Ca^{2+} cooperativity of five. Due to the non-linear relationship between Ca^{2+} and release small increments in Ca^{2+} at concentrations of more than one μ m cause massive increases in release.

D. The release of transmitter from a vesicle requires the binding of five Ca²⁺ ions to a calcium-sensing synaptic vesicle protein. In the figure Ca²⁺ binding is shown to trigger exocytosis by binding to five sensors present on a single vesicle. In reality, a single sensor binds several Ca²⁺ ions to trigger release.

depolarization to be activated (voltages positive to –40 to –20 mV are required) and thus are often referred to as *high-voltage-activated* Ca²⁺ channels. In contrast, T-type channels open in response to small depolarizations around the threshold for generating an action potential (–60 to –40 mV) and are therefore called *low-voltage-activated* Ca²⁺ channels. Because they are activated by small changes in membrane potential, the T-type channels help control excitability at the resting potential and are an important source of the excitatory current that drives the rhythmic pacemaker activity of certain cells in both brain and heart.

In neurons the rapid release of conventional transmitters associated with fast synaptic transmission is mediated mainly by the P/Q-type and N-type Ca²⁺ channels because these are the channel types concentrated at the active zone. The localization of N-type Ca²⁺ channels at the frog neuromuscular junction has been visualized using a fluorescence-labeled snail toxin that binds selectively to these channels (see Figure 12–4A). The L-type channels are not found in the active zone and thus do not normally contribute to the fast release of conventional transmitters such as ACh and glutamate. However, Ca2+ influx through L-type channels is important for slower forms of release that do not occur at specialized active zones, such as the release of neuropeptides from neurons and of hormones from endocrine cells. As we shall see below, regulation of Ca2+ influx into presynaptic terminals controls the amount of transmitter release and hence the strength of synaptic transmission.

Voltage-gated Ca²⁺ channels are responsible for certain acquired and genetic diseases. A point mutation in

the α_1 -subunit of P/Q-type channels underlies an inherited form of migraine. A mutation in the α_1 -subunit of L-type channels inhibits the voltage-dependent inactivation of these channels, and underlies Timothy syndrome, a pervasive developmental disorder involving both impaired cognitive function and a severe form of autism. Patients with Lambert-Eaton syndrome, an autoimmune disease associated with muscle weakness, make antibodies to the L-type channel α_1 -subunit that decrease total Ca²⁺ current.

Transmitter Is Released in Quantal Units

How does the influx of Ca²⁺ trigger release? Katz and his colleagues provided the key insight into this question by showing that transmitter is released in discrete amounts they called *quanta*. Each quantum of transmitter produces a postsynaptic potential of fixed size, called the *quantal synaptic potential*. The total postsynaptic potential is made up of a large number of quantal potentials. EPSPs seem smoothly graded in amplitude only because each quantal (or unit) potential is small relative to the total potential.

Katz and Fatt obtained the first clue as to the quantal nature of synaptic transmission in 1951 when they observed spontaneous postsynaptic potentials of approximately 0.5 mV in the nerve-muscle synapse of the frog. Like end-plate potentials evoked by nerve stimulation, these small depolarizing responses were largest at the site of nerve-muscle contact and decayed electrotonically with distance (see Figure 9–5). Small spontaneous potentials have since been observed in mammalian

Table 12-1 Voltage-Gated Ca	²⁺ Channels of Neurons
-----------------------------	-----------------------------------

Gene	Former name	Ca ²⁺ channel type	Tissue	Blocker	Voltage- dependence ¹	Function
Ca _v 1.1 –1.4	$\alpha_{\text{1C,D,F,S}}$	L	Muscle, neurons	Dihydropyridines	HVA	Contraction, slow release
Ca _v 2.1	$\alpha_{\rm 1A}$	P/Q	Neurons	ω-Agatoxin (spider venom)	HVA	Fast release +++
Ca _v 2.2	α_{1B}	N	Neurons	ω-Conotoxin (cone snail venom)	HVA	Fast release ++
Ca _v 2.3	$\alpha_{_{1E}}$	R	Neurons	SNX-482 (tarantula venom)	HVA	Fast release +
$Ca_{v}3.1 - 3.3$	$\alpha_{\text{1G,H,I}}$	T	Muscle, neurons	Mibefradil (limited selectivity)	LVA	Pacemaker firing

¹HVA, high voltage activated; LVA, low voltage activated.

muscle and in central neurons. Because the postsynaptic potentials at vertebrate nerve-muscle synapses are called *end-plate potentials*, Fatt and Katz called these spontaneous potentials *miniature end-plate potentials*.

Several results convinced Fatt and Katz that the miniature end-plate potentials represented responses to the release of small amounts of ACh, the neurotransmitter used at the nerve-muscle synapse. The time course of the miniature end-plate potentials and the effects of various drugs on them are indistinguishable from the properties of the end-plate potential. Like the endplate potentials, the miniature end-plate potentials are enhanced and prolonged by prostigmine, a drug that blocks hydrolysis of ACh by acetylcholinesterase. Conversely, they are reduced and finally abolished by agents that block the ACh receptor. The miniature endplate potentials represent responses to small packets of transmitter that are spontaneously released from the presynaptic nerve terminal in the absence of an action potential. Their frequency can be increased by a small depolarization of the presynaptic terminal. They disappear if the presynaptic motor nerve degenerates and reappear when a new motor synapse is formed.

What could account for the small, fixed size of the miniature end-plate potential (around 0.5–1 mV)? Del Castillo and Katz first tested the possibility that each event represents a response to the opening of a *single* ACh receptor-channel. Small amounts of ACh applied to the frog muscle end-plate elicited depolarizing postsynaptic responses that were much smaller than the 0.5 mV response of a miniature end-plate potential. This finding made it clear that the miniature end-plate potential represents the opening of more than one ACh receptor-channel. In fact, Katz and Miledi were later able to estimate the voltage response to the elementary current through a single ACh receptor-channel as being only approximately 0.3 µV (see Chapter 9). Based on this estimate a miniature end-plate potential of 0.5 mV would represent the summation of the elementary currents of approximately 2,000 channels. Later work showed that a miniature end-plate potential is the response to the synchronous release of approximately 5,000 molecules of ACh.

What is the relationship of the large end-plate potential evoked by nerve stimulation and the small, spontaneous miniature end-plate responses? This question was addressed by del Castillo and Katz in a study of synaptic signaling at the nerve-muscle synapse bathed in a solution low in Ca²⁺. Under this condition the end-plate potential is reduced markedly, from the normal 70 mV to about 0.5 to 2.5 mV. Moreover, the amplitude of each successive end-plate potential now varies randomly from one stimulus to the next; often no

response can be detected at all (termed *failures*). However, the minimum response above zero—the unit EPSP in response to a presynaptic action potential—is identical in amplitude (approximately 0.5 mV) and shape to the spontaneous miniature end-plate potentials. Importantly, the amplitude of each end-plate potential is an integral multiple of the unit potential (Figure 12–6).

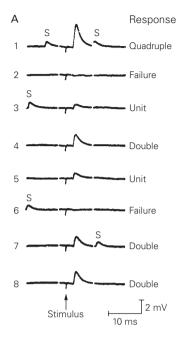

Now del Castillo and Katz could ask: How does the rise of intracellular Ca²⁺ that accompanies each action potential affect the release of transmitter? They found that increasing the external Ca²⁺ concentration does not change the amplitude of the unit synaptic potential. However, the proportion of failures decreases and the incidence of higher-amplitude responses (composed of multiple quantal units) increases. These observations show that an increase in external Ca²⁺ concentration does not enhance the *size* of a quantum of transmitter (that is, the number of ACh molecules in each quantum) but rather acts to increase the average number of quanta that are released in response to a presynaptic action potential (Box 12–1). The greater the Ca²⁺ influx into the terminal, the larger the number of transmitter quanta released.

Thus three findings led del Castillo and Katz to conclude that transmitter is released in packets with a fixed amount of transmitter, a quantum: The amplitude of the end-plate potential varies in a stepwise manner at low levels of ACh release, the amplitude of each step increase is an integral multiple of the unit potential, and the unit potential has the same mean amplitude as that of the spontaneous miniature end-plate potentials.

In the absence of an action potential the rate of quantal release is low—only one quantum per second is released spontaneously at the end-plate. In the presence of a normal concentration of extracellular Ca²⁺ the firing of an action potential in the presynaptic terminal at the vertebrate nerve-muscle synapse releases approximately 150 quanta, each approximately 0.5 mV in amplitude, resulting in a large end-plate potential. Thus when Ca²⁺ enters the presynaptic terminal during an action potential, it dramatically increases the rate of quantal release by a factor of 150,000, triggering the synchronous release of about 150 quanta in about one millisecond.

Transmitter Is Stored and Released by Synaptic Vesicles

What anatomical features of the cell might account for the quantum of transmitter? The physiological observations indicating that transmitter is released in fixed quanta coincided with the discovery, through electron microscopy, of accumulations of small clear vesicles in

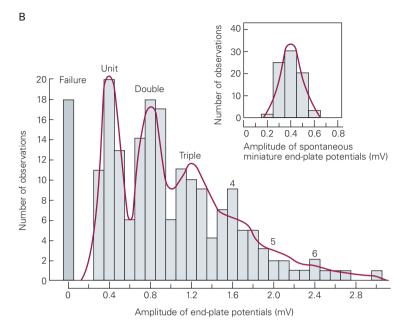

Figure 12–6 Neurotransmitter is released in fixed increments. Each increment or quantum of transmitter produces a unit excitatory postsynaptic potential (EPSP) of fixed amplitude. The amplitude of the EPSP evoked by nerve stimulation is thus equal to the amplitude of the unit EPSP multiplied by the number of quanta of transmitter released.

A. Intracellular recordings from a muscle fiber at the end-plate show the change in postsynaptic potential when eight consecutive stimuli of the same size are applied to the motor nerve. To reduce transmitter release and to keep the end-plate potentials small, the tissue is bathed in a calcium-deficient (and magnesium-rich) solution. The postsynaptic responses to the nerve stimulus vary. Two presynaptic impulses elicit no EPSP (failures), two produce unit potentials, and the others produce EPSPs that are approximately two to four times the amplitude of the unit potential. Note that the spontaneous miniature end-plate potentials (S), which occur at random intervals in the traces, are the same size as the unit potential. (Adapted, with permission, from Liley 1956.)

B. After many end-plate potentials are recorded, the number of EPSPs corresponding to a given amplitude is plotted as a function of this amplitude in the histogram shown here. The distribution of responses falls into a number of peaks. The first peak, at 0 mV, represents failures. The first peak of responses, at 0.4 mV, represents the unit potential, the smallest elicited response. The unit response has the same amplitude as the

spontaneous miniature end-plate potentials (inset), indicating that the unit response is caused by the release of a single quantum of transmitter. The other peaks in the histogram are integral multiples of the amplitude of the unit potential; that is, responses are composed of two, three, four, or more quantal events.

The number of responses under each peak divided by the total number of events in the entire histogram is the probability that a single presynaptic action potential triggers the release of the number of quanta that corresponds to the peak. For example, if there are 30 events in the peak corresponding to the release of two quanta out of a total of 100 events recorded, the probability that a presynaptic action potential releases exactly two quanta is 30/100 or 0.3. This probability follows a Poisson distribution (red curve). This theoretical distribution is composed of the sum of several Gaussian functions. The spread of the unit peak (standard deviation of the Gaussian function) reflects the fact that the amount of transmitter in a quantum, and hence the amplitude of the quantal postsynaptic response, varies randomly about a mean value. The successive Gaussian peaks widen progressively because the variability associated with each guantal event sums linearly with the number of guanta. The distribution of amplitudes of the spontaneous miniature potentials (inset) is fit by a Gaussian curve whose width is identical to that of the Gaussian curve for the unit synaptic responses. (Adapted, with permission, from Boyd and Martin 1956.)

the presynaptic terminal. Del Castillo and Katz speculated that the vesicles are organelles for the storage of transmitter, each vesicle stores one quantum of transmitter (amounting to several thousand molecules), and each vesicle releases its entire contents into the synaptic cleft in an all-or-none manner at sites specialized for release.

The sites of release, the active zones, contain a cloud of synaptic vesicles that cluster above a fuzzy electron-dense material attached to the internal face of the presynaptic membrane (see Figure 12–4A). At all rapid synapses the vesicles are typically clear, small, and ovoid, with a diameter of approximately 40 nm. Although most synaptic vesicles do not contact the

Box 12–1 Calculating the Probability of Transmitter Release

The release of a quantum of transmitter is a random event. The fate of each quantum of transmitter in response to an action potential has only two possible outcomes—the quantum is or is not released. This event resembles a binomial or Bernoulli trial (similar to tossing a coin in the air to determine whether it comes up heads or tails).

The probability of a quantum being released by an action potential is independent of the probability of other quanta being released by that action potential. Therefore, for a population of releasable quanta, each action potential represents a series of independent binomial trials (comparable to tossing a handful of coins to see how many coins come up heads).

In a binomial distribution p stands for the average probability of success (ie, the probability that any given quantum will be released) and q (equal to 1-p) stands for the mean probability of failure. Both the average probability (p) that an individual quantum will be released and the store (n) of readily releasable quanta are assumed to be constant. (Any reduction in the store is assumed to be quickly replenished after each stimulus.) The product of n and p yields an estimate m of the mean number of quanta that are released to make up the end-plate potential. This mean is called the *quantal content* or *quantal output*.

Calculation of the probability of transmitter release can be illustrated with the following example. Consider a terminal that has a releasable store of five quanta (n = 5). If we assume that p = 0.1, then q (the probability that an individual quantum is not released from the terminals) is 1 - p, or 0.9. We can now determine the probability that a stimulus will release no quanta (failure), a single quantum, two quanta, three quanta, or any number of quanta (up to n).

The probability that none of the five available quanta will be released by a given stimulus is the product of the individual probabilities that each quantum will not be released: $q^5 = (0.9)^5$, or 0.59. We would thus expect to see 59 failures in a hundred stimuli. The probabilities of observing zero, one, two, three, four, or five quanta are represented by the successive terms of the binomial expansion:

$$(q+p)^5 = q^5$$
 (failures) + 5 q^4p (1 quantum)
+ 10 q^3p^2 (2 quanta) + 10 q^2p^3 (3 quanta)
+ 5 qp^4 (4 quanta) + p^5 (5 quanta).

Thus, in 100 stimuli the binomial expansion would predict 33 unit responses, 7 double responses, 1 triple response, and 0 quadruple or quintuple responses.

Values for *m* vary from approximately 100 to 300 at the vertebrate nerve-muscle synapse, the squid giant synapse, and *Aplysia* central synapses, to as few as 1 to 4 in the synapses of the sympathetic ganglion and spinal cord of vertebrates. The probability of release *p* also varies, ranging from as high as 0.7 at the neuromuscular junction in the frog and 0.9 in the crab down to around 0.1 at some central synapses. Estimates for *n* range from 1,000 (at the vertebrate nerve-muscle synapse) to 1 (at single terminals of central neurons).

The parameters n and p are statistical terms; the physical processes represented by them are not yet completely understood. As discussed in this chapter, transmitter is packaged in synaptic vesicles and a quantum of transmitter corresponds to the all-or-none release of the contents of a vesicle. Although the parameter n was initially assumed to represent the number of readily releasable (or available) quanta of transmitter, it is now thought to reflect the number of release sites or active zones in the presynaptic terminals that are loaded with vesicles containing neurotransmitter.

Although an active zone has a number of docked vesicles, there is evidence that a presynaptic action potential can trigger the exocytosis of at most one vesicle per active zone. Although the number of release sites is thought to be fixed, the fraction that is loaded with vesicles is thought to be variable.

The parameter p probably represents a compound probability depending on at least two processes: the number of vesicles that have been loaded or docked onto a release site (a process referred to as vesicle mobilization) and the probability that an action potential will discharge a quantum of transmitter from a given vesicle docked at the active zone. This probability is thought to depend on Ca^{2+} influx during an action potential.

The quantal size *a* is the response of the postsynaptic membrane to the release of a single quantum of transmitter. Quantal size depends largely on the properties of the postsynaptic cell, such as the input resistance and capacitance (which can be independently estimated) and the responsiveness of the postsynaptic membrane to the transmitter substance. This can also be measured by the postsynaptic membrane's response to the application of a constant amount of transmitter.

The mean size of a synaptic response E evoked by an action potential thus depends on the product of the total number of quanta present, the probability that an individual quantum is released, and the size of the response to a quantum: $E = n \cdot p \cdot a$.

active zone, some are physically bound. These are called the *docked* vesicles and are thought to be the ones immediately available for release. At the neuromuscular junction the active zones are linear structures (see Figure 12–4), whereas in central synapses they are discishaped structures approximately $0.1~\mu\text{m}^2$ in area with dense projections pointing into the cytoplasm. Active zones are always precisely apposed to the postsynaptic membrane patches that contain the neurotransmitter receptors. Thus presynaptic and postsynaptic specializations are functionally and morphologically attuned to each other. As we shall learn later, several key active zone proteins involved in transmitter release have now been identified and characterized.

Quantal transmission has been demonstrated at all chemical synapses so far examined with only one exception: at the synapse between photoreceptors and bipolar neurons in the retina (Chapter 26). Nevertheless, the efficacy of transmitter release from a single presynaptic cell onto a single postsynaptic cell varies widely in the nervous system and depends on several factors: (1) the number of synapses between a pair of presynaptic and postsynaptic cells (ie, the number of presynaptic boutons that contact the postsynaptic cell); (2) the number of active zones in an individual synaptic terminal; and (3) the probability that a presynaptic action potential will trigger release of one or more quanta of transmitter at an active zone (Box 12–1).

In the central nervous system most presynaptic terminals have only a single active zone where an action potential usually releases at most a single quantum of transmitter in an all-or-none manner. However at some central synapses, such as the calyx of Held, the presynaptic terminal may contain many active zones and thus can release a large number of quanta in response to a single presynaptic action potential. Central neurons also differ in the number of synapses that a typical presynaptic cell makes with a typical postsynaptic cell. Whereas most central neurons form only a few synapses with any one postsynaptic cell, a single climbing fiber forms up to 10,000 terminals on a single Purkinje neuron in the cerebellum! Finally, the mean probability of transmitter release from a single active zone also varies widely among different presynaptic terminals, from less than 0.1 (that is, a 10% chance that a presynaptic action potential will trigger release of a vesicle) to greater than 0.9. This wide range of probabilities can even be seen among the individual boutons at different synapses between one specific type of presynaptic cell and one specific type of postsynaptic cell.

Thus central neurons vary widely in the efficacy and reliability of synaptic transmission. Synaptic reliability is defined as the probability that an action potential in

a presynaptic cell leads to some measurable response in the postsynaptic cell—that is, the probability that a presynaptic action potential releases one or more quanta of transmitter. Efficacy refers to the mean amplitude of the synaptic response, which depends on both the reliability of synaptic transmission and on the mean size of the response when synaptic transmission does occur.

Most central neurons communicate at synapses that have a low probability of transmitter release. The high failure rate of release at most central synapses (ie, their low release probability) is not a design defect but serves a purpose. As we discuss below, this feature allows transmitter release to be regulated over a wide dynamic range, which is important for learning and memory. In synaptic connections where a low probability of release is deleterious for function, this limitation is overcome by simply having many active zones in one synapse, as is the case at the calyx of Held and the nerve-muscle synapse. Both contain hundreds of independent active zones, so an action potential reliably releases 150 to 250 quanta, ensuring that a presynaptic signal is always followed by a postsynaptic action potential. Reliable transmission at the neuromuscular junction is essential for survival. An animal would not survive if its ability to move away from a predator was hampered by a low-probability response.

Not all chemical signaling between neurons depends on synapses. Some substances, such as certain lipid metabolites and the gas nitric oxide (see Chapter 11), can diffuse across the lipid bilayer of the membrane. Others can be moved out of nerve endings by carrier proteins if their intracellular concentration is sufficiently high. Plasma membrane transporters for glutamate or γ-aminobutyric acid (GABA) normally take up transmitter into a cell from the synaptic cleft following a presynaptic action potential (see Chapter 13). However, in certain glial cells of the retina, the direction of glutamate transport can be reversed under certain conditions, causing glutamate to leave the cell through the transporter into the synaptic cleft. Still other substances simply leak out of nerve terminals at a low rate. Surprisingly, approximately 90% of the ACh that leaves the presynaptic terminals at the neuromuscular junction does so through continuous leakage. This leakage is ineffective, because it is diffuse and not targeted to receptors at the end-plate region, and because it is continuous and low level rather than synchronous and concentrated.

Synaptic Vesicles Discharge Transmitter by Exocytosis and Are Recycled by Endocytosis

The quantal hypothesis of del Castillo and Katz has been amply confirmed by direct experimental evidence that synaptic vesicles do indeed package neurotransmitter and that they release their contents by directly fusing with the presynaptic membrane, a process termed *exocytosis*.

Forty years ago Victor Whittaker discovered that the synaptic vesicles in the motor nerve terminals of the electric organ of the fish *Torpedo* contain a high concentration of ACh. Later, Thomas Reese and John Heuser and their colleagues obtained electron micrographs that caught vesicles in the act of exocytosis. To observe the brief exocytotic event, they rapidly froze the nervemuscle synapse by immersing it in liquid helium at precisely defined intervals after the presynaptic nerve was stimulated. In addition, they increased the number of quanta of transmitter discharged with each nerve impulse by applying the drug 4-aminopyridine, a compound that blocks certain voltage-gated K⁺ channels, which increases the duration of the action potential, thereby enhancing Ca²⁺ influx.

These techniques provided clear images of synaptic vesicles at the active zone during exocytosis. Using a technique called freeze-fracture electron microscopy, Reese and Heuser noted deformations of the presynaptic membrane along the active zone immediately after synaptic activity, which they interpreted as invaginations of the cell membrane caused by fusion of synaptic vesicles. These deformations lay along one or two rows of unusually large intramembranous particles, visible along both margins of the presynaptic density and now thought to be the voltage-gated Ca²⁺ channels (Figure 12-7). The particle density (approximately 1,500 per µm²) is approximately that of the Ca²⁺ channels essential for transmitter release. Moreover, the proximity of the particles to the release site is consistent with the short time interval between the onset of the Ca²⁺ current and the release of transmitter.

Finally, Heuser and Reese found that these deformations are transient; they occur only when vesicles are discharged and do not persist after transmitter has been released. Thin-section electron micrographs revealed a number of omega-shaped (Ω) structures that have the appearance of synaptic vesicles that have just fused with the membrane, prior to the complete collapse of the vesicle membrane into the plasma membrane (Figure 12–7B). Heuser and Reese confirmed this idea by showing that the number of Ω -shaped structures is directly correlated with the size of the EPSP when they varied the concentration of 4-aminopyridine to alter the amount of transmitter release. These morphological studies provide striking evidence that transmitter is released from synaptic vesicles by means of exocytosis.

Following exocytosis, the excess membrane added to the presynaptic terminal is retrieved. When Heuser

and Reese obtained images of presynaptic terminals 10 to 20 seconds after stimulation, they observed new structures at the plasma membrane, the coated pits, which represent membrane retrieval through the process of endocytosis (Figure 12–7C). Several seconds later the coated pits are seen to pinch off from the membrane and appear as coated vesicles in the cytoplasm. As we will see below, endocytosis through coated pit formation represents one of several means of vesicle membrane retrieval.

Capacitance Measurements Provide Insight into the Kinetics of Exocytosis and Endocytosis

In certain neurons with large presynaptic terminals the increase in surface area of the plasma membrane during exocytosis can be detected in electrical measurements as increases in membrane capacitance. As we saw in Chapter 6, the capacitance of the membrane is proportional to its surface area. Neher discovered that one could use measurements of capacitance to monitor exocytosis in secretory cells.

In adrenal chromaffin cells (which release epinephrine and norepinephrine) and in mast cells of the rat peritoneum (which release histamine and serotonin) individual dense-core vesicles are large enough to permit measurement of the increase in capacitance associated with fusion of a single vesicle. Release of transmitter in these cells is accompanied by stepwise increases in capacitance, followed somewhat later by stepwise decreases, which reflect the retrieval and recycling of the excess membrane (Figure 12–8).

In neurons the changes in capacitance caused by fusion of single, small synaptic vesicles are usually too low to resolve. In certain favorable synaptic preparations that release large numbers of vesicles (such as the giant presynaptic terminals of bipolar neurons in the retina), membrane depolarization triggers a transient smooth rise in the total capacitance of the terminal as a result of the exocytosis and retrieval of the membrane from hundreds of individual synaptic vesicles (Figure 12–8C). These results provide direct measurements of the rates of membrane fusion and retrieval.

Exocytosis Involves the Formation of a Temporary Fusion Pore

Morphological studies of mast cells using rapid freezing suggest that exocytosis depends on the formation of a temporary fusion pore that spans the membranes of the vesicle and plasma membranes. In electrophysiological studies of capacitance increases in mast cells, a channel-like fusion pore was detected in

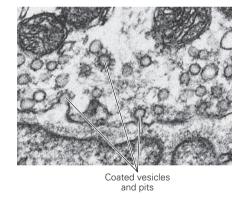

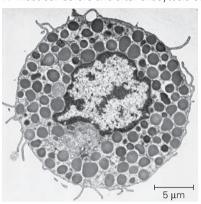

Figure 12-7 Synaptic vesicles release transmitter by exocytosis and are retrieved by endocytosis. The images on the left are freeze-fracture electron micrographs at a neuromuscular junction. The views shown are of the cytoplasmic leaflet of the presynaptic membrane looking up from the synaptic cleft. The images on the right are thin-section electron micrographs showing cross-section views of the presynaptic terminal, synaptic cleft, and postsynaptic muscle membrane. (Reproduced, with permission, from Heuser and Reese 1981.)

A. Parallel rows of intramembranous particles arrayed on either side of an active zone are thought to be the voltage-gated Ca²⁴ channels essential for transmitter release. The thin-section image at right shows the synaptic vesicles adjacent to the active zone.

B. Synaptic vesicles release transmitter by fusing with the plasma membrane (exocytosis). Here synaptic vesicles are caught in the act of fusing with the plasma membrane by rapid freezing of the tissue within 5 ms after a depolarizing stimulus. Each depression in the plasma membrane represents the fusion of one synaptic vesicle. In the micrograph at right vesicle fusion is observed as Ω -shaped structures.

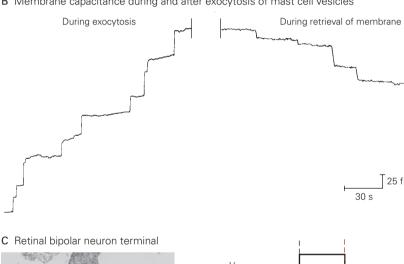

C. After exocytosis, synaptic vesicle membrane is retrieved by endocytosis. Within approximately 10 seconds after fusion of the vesicles with the presynaptic membrane, coated pits form. After another 10 seconds the coated pits begin to pinch off by endocytosis to form coated vesicles. These vesicles include the membrane proteins of the original synaptic vesicle and also molecules captured from the external medium. The vesicles are recycled at the terminals or are transported to the cell body, where the membrane constituents are degraded or recycled (see Chapter 4).

the electrophysiological recordings prior to complete fusion of vesicles and cell membranes. This fusion pore starts out with a single-channel conductance of approximately 200 pS, similar to that of gap-junction channels, which also bridge two membranes. During exocytosis the pore rapidly dilates, probably from around 5 to 50 nm in diameter, and the conductance increases dramatically (Figure 12–9A).

The fusion pore is not just an intermediate structure leading to exocytosis of transmitter, as transmitter can be released through the pore prior to full fusion. This was first shown by amperometry, a method that uses an extracellular carbon-fiber electrode to detect certain amine neurotransmitters, such as serotonin, based on an electrochemical reaction between the transmitter and the electrode that generates an electrical current proportional to the local transmitter concentration. Firing of an action potential in serotonergic cells leads to a large transient increase in electrode current, corresponding to the exocytosis of the contents of a single dense-core vesicle. In some instances these large transient increases are preceded by smaller, longerlasting current signals that reflect leakage of transmitter through a fusion pore that flickers open and closed several times prior to complete fusion (Figure 12–9B).

Transmitter can also be released solely through transient fusion pores, that is, without full collapse of the vesicle membrane into the plasma membrane. Capacitance measurements for exocytosis of both large dense-core vesicles and small clear vesicles in neuroendocrine cells show that the fusion pore can open and close rapidly and reversibly. The reversible opening

and closing of a fusion pore represents a very rapid method of membrane retrieval. The circumstances under which the small clear vesicles at fast synapses discharge transmitter through a fusion pore, as opposed to full membrane collapse, are uncertain.

The Synaptic Vesicle Cycle Involves Several Steps

When firing at high frequency, a typical neuron is able to maintain a high rate of transmitter release. This can result in the exocytosis of a large number of vesicles, more than the number originally present within the presynaptic terminal. To prevent the supply of vesicles from being rapidly depleted, used vesicles are rapidly retrieved and recycled. Because nerve terminals are usually some distance from the cell body, replenishing vesicles by synthesis in the cell body and transport to the terminals would be too slow to be practical.

Synaptic vesicles are released and reused in a simple cycle (Figure 12–10A). Vesicles fill with neurotransmitter and cluster in the nerve terminal. They then dock at the active zone where they undergo a complex *priming* process that makes vesicles competent to respond to the Ca²⁺ signal that triggers the fusion process.

Three mechanisms exist for retrieving the synaptic vesicle membrane following exocytosis and each has a distinct time course. The first, most rapid mechanism involves the reversible opening and closing of the fusion pore, without the full collapse of the vesicle membrane into the plasma membrane (Figure 12–10B1). In the *kiss-and-stay* pathway the vesicle remains at the active zone after the fusion pore closes, ready for a second

Figure 12–8 (Opposite) Changes in capacitance reveal the time course of exocytosis and endocytosis.

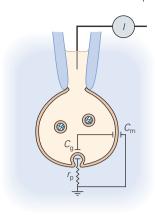

A. Electron micrographs show a mast cell before (left) and after (right) inducing exocytosis. Mast cells are secretory cells of the immune system that contain large dense-core vesicles filled with the transmitter histamine. Exocytosis of the secretory vesicles is normally triggered by the binding of antigen complexed to an immunoglobulin (lgE). Under experimental conditions massive exocytosis can be triggered by the inclusion of a nonhydrolyzable analog of guanosine triphosphate (GTP) in an intracellular recording electrode. (Reproduced, with permission, from Lawson et al. 1977.)

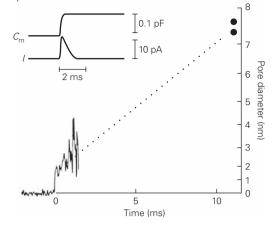

B. Stepwise increases in capacitance reflect the successive fusion of individual secretory vesicles with the mast cell membrane. The step increases are unequal because of variability in the membrane area of the vesicles. After exocytosis the membrane added through fusion is retrieved through endocytosis. Endocytosis of individual vesicles gives rise to the stepwise decreases in membrane capacitance. In this way the cell maintains a constant size. (The units are in femtofarads, fF, where

 $1~fF=0.1~\mu m^2$ of membrane area.) (Adapted, with permission, from Fernandez, Neher, and Gomperts 1984.)

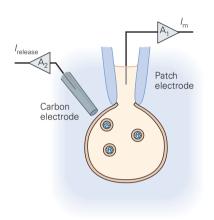

C. The giant presynaptic terminals of bipolar neurons in the retina are more than 5 µm in diameter, permitting direct patchclamp recordings of membrane capacitance and Ca²⁺ current. A brief depolarizing voltage-clamp step in membrane potential $(V_{\rm m})$ elicits a large sustained Ca²⁺ current $(I_{\rm Ca})$ and a rise in the cytoplasmic Ca²⁺ concentration, [Ca]. This results in the fusion of several thousand small synaptic vesicles with the cell membrane, leading to an increase in total membrane capacitance. The increments in capacitance caused by fusion of individual vesicles are too small to resolve. As the internal Ca2+ concentration falls back to its resting level upon repolarization, the extra membrane area is retrieved and capacitance returns to its baseline value. The increases in capacitance and Ca²⁺ concentration outlast the brief depolarization and Ca²⁺ current (note different time scales) because of the relative slowness of endocytosis and Ca2+ metabolism. (Micrograph reproduced, with permission, from Zenisek et al. 2004; traces adapted, with permission, from von Gersdorff and Matthews 1994.)

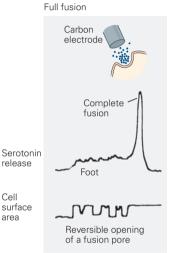

A Electrical events associated with opening of fusion pore

B Transmitter release through fusion pore

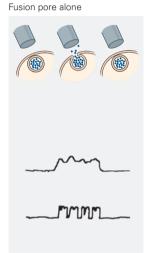

Figure 12–9 Some transmitter is released through temporary fusion pores.

A. A patch clamp is used to record membrane current associated with the opening of a fusion pore. As a vesicle fuses with the plasma membrane, the capacitance of the vesicle (C_0) is initially connected to the capacitance of the rest of the cell membrane ($C_{\rm m}$) through the high resistance of the fusion pore ($r_{\rm o}$). Because the membrane potential of the vesicle (lumenal side negative) is normally much more negative than the membrane potential of the cell, charge flows from the vesicle to the cell membrane during fusion. This transient current (I) is associated with the increase in membrane capacitance (C_m). The magnitude of the conductance of the fusion pore (g_p) can be calculated from the time constant of the transient current according to $\tau = C_{\rm q} r_{\rm p} = C_{\rm q}/g_{\rm p}$. The pore diameter can be calculated from the pore conductance, assuming that the pore spans two lipid bilayers and is filled with a solution whose resistivity is equal to that of the cytoplasm. In the plot on the right the pore shows an initial conductance of approximately 200 pS, similar to the conductance of a gap-junction channel, corresponding to a pore diameter of approximately 2 nm. The poor diameter and conductance rapidly increase as the pore dilates to approximately 7 to 8 nm in 10 ms (filled circles). (Adapted, with permission, from Monck and Fernandez 1992: Spruce et al. 1990.)

B. Transmitter release is measured by amperometry. A cell is voltage-clamped with an intracellular patch electrode while an

extracellular carbon fiber is pressed against the cell surface. A large voltage applied to the tip of the carbon electrode oxidizes certain amine transmitters (such as serotonin or norepinephrine). This oxidation of one molecule generates one or more free electrons, which results in an electrical current that is proportional to the amount of transmitter release. The current can be recorded through an amplifier (A₂) connected to the carbon electrode. Membrane current and capacitance are recorded through the patch electrode amplifier (A₁). Recordings of transmitter release and capacitance measurements from mast cell secretory vesicles are shown at the right. These records indicate that serotonin may be released through the reversible opening and closing of the fusion pore prior to full fusion or by reversible fusion pore opening and closing through the fusion pore alone, that is without full fusion. During the brief fusion pore openings small amounts of transmitter escape through the pore, resulting in a low-level signal (a foot) that precedes a large spike of transmitter release upon full fusion (see inset for illustration). During the foot the cell membrane capacitance (proportional to cell surface area) undergoes reversible step-like changes as the fusion pore opens and closes. Sometimes the reversible opening and closing is not followed by full fusion, such that transmitter is released through the fusion pore alone. (Adapted, with permission, from Neher 1993.)

release event. In the *kiss-and-run* pathway the vesicle leaves the active zone after the fusion pore closes, but is competent for rapid rerelease. Vesicles are thought to be preferentially recycled through these pathways during stimulation at low frequencies.

Stimulation at higher frequencies recruits a second, slower recycling pathway that uses clathrin to retrieve the vesicle membrane after fusion with the plasma membrane (see Figure 12–10B2). (The clathrin-coated vesicle membranes are the coated pits observed by Heuser and Reese.) In this pathway the retrieved vesicular membrane must be recycled through an endosomal compartment before the vesicles can be reused. Clathrin-mediated recycling requires up to a

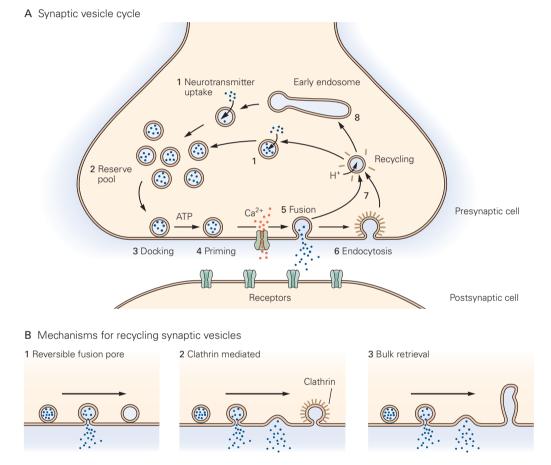

Figure 12–10 The synaptic vesicle cycle.

A. Synaptic vesicles are filled with neurotransmitters by active transport (step 1) and join the vesicle cluster that may represent a reserve pool (step 2). Filled vesicles dock at the active zone (step 3) where they undergo an ATP-dependent priming reaction (step 4) that makes them competent for calcium-triggered fusion (step 5). After discharging their contents, synaptic vesicles are recycled through one of several routes (see part B). In one common route, vesicle membrane is retrieved via clathrinmediated endocytosis (step 6) and recycled directly (step 7) or by endosomes (step 8).

B. Retrieval of vesicles after transmitter discharge is thought to occur via three mechanisms, each with distinct kinetics. **1.** A reversible fusion pore is the most rapid mechanism for reusing vesicles. The vesicle membrane does not completely fuse with the plasma membrane and transmitter is released through the

fusion pore. Vesicle retrieval requires only the closure of the fusion pore and thus can occur rapidly, in tens to hundreds of milliseconds. This pathway may predominate at lower to normal release rates. The spent vesicle may either remain at the membrane (kiss-and-stay) or relocate from the membrane to the reserve pool of vesicles (kiss-and-run). 2. In the classical pathway excess membrane is retrieved through endocytosis by means of clathrin-coated pits. These pits are found throughout the axon terminal except at the active zones. This pathway may be important at normal to high rates of release. 3. In the bulk retrieval pathway, excess membrane reenters the terminal by budding from uncoated pits. These uncoated cisternae are formed primarily at the active zones. This pathway may be used only after high rates of release and not during the usual functioning of the synapse. (Adapted, with permission, from Schweizer, Betz, and Augustine 1995; Südhof 2004.)

minute for completion, and appears to shift from the active zone to the membrane surrounding the active zone (see Figure 12–7).

A third mechanism operates after prolonged high-frequency stimulation. Under these conditions large membranous invaginations into the presynaptic terminal are visible, which are thought to reflect membrane recycling through a process called *bulk retrieval* (Figure 12–10B3).

Exocytosis of Synaptic Vesicles Relies on a Highly Conserved Protein Machinery

Biochemists have isolated and purified many key proteins of synaptic vesicles, as well as their interacting partners in the plasma membrane (Figure 12–11). One key class of vesicle proteins are the neurotransmitter transporters (Chapter 13). These transmembrane proteins use energy stored in a proton gradient across the vesicle membrane to pump transmitter molecules into the vesicle from the cytoplasm, against their concentration gradient.

Other synaptic vesicle proteins target vesicles to their release sites, participate in the discharge of transmitter by exocytosis, and mediate recycling of the vesicle membrane. The protein machinery involved in these three steps is conserved from worms to humans, and forms the basis for the regulated release of neurotransmitter. We consider each of these steps in turn.

The Synapsins Are Important for Vesicle Restraint and Mobilization

The vesicles outside the active zone represent a reserve pool of transmitter. Paul Greengard discovered a family of proteins, *synapsins*, that are important regulators of the reserve pool of vesicles (Figure 12–11). Synapsins are peripheral membrane proteins that are bound to the cytoplasmic surface of synaptic vesicles. They also bind adenosine triphosphate (ATP) and actin.

The synapsins are substrates for both protein kinase A and Ca²⁺/calmodulin-dependent protein kinase I. When the nerve terminal is depolarized and Ca²⁺ enters, the synapsins become phosphorylated by the kinase and are thus released from the vesicles, a step that is thought to mobilize the reserve pool of vesicles for transmitter release. Indeed, genetic deletion of synapsins or application of a synapsin antibody leads to a decrease in the number of synaptic vesicles in the nerve terminal and a decrease in the ability of a terminal to maintain a high rate of transmitter release during repetitive stimulation.

SNARE Proteins Catalyze Fusion of Vesicles with the Plasma Membrane

Because a membrane bilayer is a stable structure, fusion of the synaptic vesicle and plasma membrane must overcome a large unfavorable activation energy. This is accomplished by a family of fusion proteins now referred to as SNAREs (soluble *N*-ethylmaleimidesensitive factor attachment receptors) (Figure 12–12).

SNAREs are universally involved in membrane fusion, from yeast to humans. They mediate both constitutive membrane trafficking during the movement of proteins from the endoplasmic reticulum to the Golgi apparatus to the plasma membrane, as well as synaptic vesicle trafficking important for regulated exocytosis. SNAREs have a conserved protein sequence, the SNARE motif, that is 60 residues long. They come in two forms. Vesicle SNAREs or v-SNAREs (also referred to as R-SNAREs because they contain an important central arginine residue) reside in the vesicle membranes. Target-membrane SNAREs or t-SNAREs (also referred to as Q-SNAREs because they contain an important glutamine residue) are present in target membranes, such as the plasma membrane. In biochemical experiments using purified v-SNAREs and t-SNAREs in solution, four SNARE motifs bind tightly to each other to form an α-helical coiled-coil complex (Figure 12–12B).

Each synaptic vesicle contains a single type of v-SNARE called synaptobrevin (also called vesicle-associated membrane protein or VAMP). By contrast, the presynaptic active zone contains two types of t-SNARE proteins, syntaxin and SNAP-25. (Synaptobrevin and syntaxin have one SNARE motif; SNAP-25 has two.) The first clue that synaptobrevin, syntaxin, and SNAP-25 are all involved in fusion of the synaptic vesicle with the plasma membrane came from the finding that all three proteins are substrates for botulinum and tetanus toxins, bacterial proteases that are potent inhibitors of transmitter release. James Rothman then provided the crucial insight that these three proteins interact in a tight biochemical complex.

How does formation of the SNARE complex drive synaptic vesicle fusion? During exocytosis the SNARE motif of synaptobrevin, on the synaptic vesicle, forms a tight complex with the SNARE motifs of SNAP-25 and syntaxin, on the plasma membrane (Figure 12–12). The crystal structure of the SNARE complex suggests that this complex draws the membranes together. The ternary complex of synaptobrevin, syntaxin, and SNAP-25 is extraordinarily stable. The energy released in its assembly is thought to draw the negatively charged phospholipids of the vesicle and plasma membranes in close apposition, forcing them into a prefusion

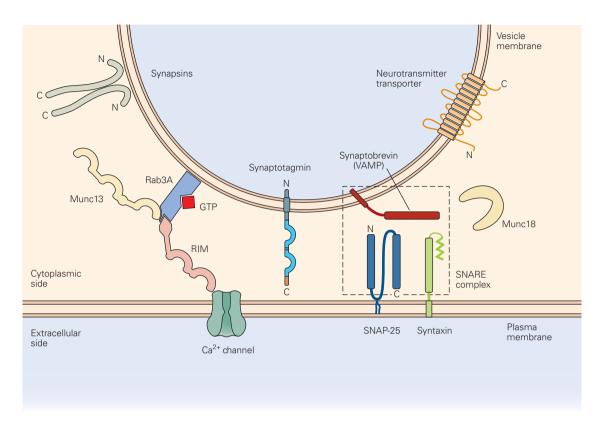

Figure 12–11 A protein network regulates synaptic vesicle exocytosis and membrane cycling. The drawing shows some of the key synaptic vesicle and plasma membrane proteins at the active zone and their interactions. Exocytosis is mediated by the formation of the SNARE complex (dotted lines), which results from the tight interaction between the protein synaptobrevin (or VAMP) in the vesicle membrane and the proteins syntaxin and SNAP-25 in the plasma membrane. Munc18 interacts with the SNARE complex and is essential for vesicle fusion. A second protein complex occurs when the vesicle

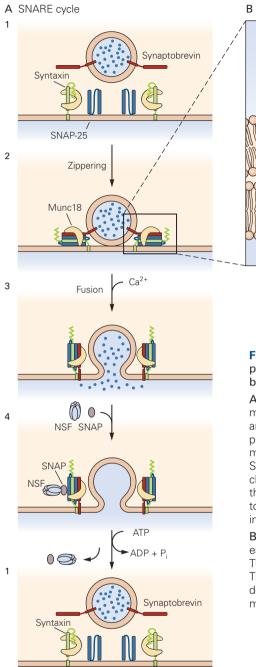

protein Rab3 binds to the cytoplasmic proteins Munc13 and RIM. The SNARE and Rab3 complexes are functionally linked because of an interaction between syntaxin and Munc13. The syntaxin-Munc13 complex likely inhibits the formation of the SNARE complex. The vesicle protein synaptotagmin serves as the Ca²⁺ sensor for exocytosis and may also interact with RIM. Synaptic vesicles also contain membrane transporters necessary for neurotransmitter uptake. A peripheral vesicle protein, synapsin, is important in regulating the availability of vesicles from the reserve pool.

intermediate state (Figure 12–12). Such an unstable state may start the formation of the fusion pore and account for the rapid opening and closing (flickering) of the fusion pore observed in electrophysiological measurements. The SNARE proteins may form part of the fusion pore based upon studies that have shown that mutations in the transmembrane region of syntaxin alter the single-channel conductance of the fusion pore.

However, the SNAREs do not fully account for fusion of the synaptic vesicle and plasma membranes. Reconstitution experiments with purified proteins in lipid vesicles indicate that synaptobrevin, syntaxin, and SNAP-25 can catalyze fusion; but the in vitro reaction shows little regulation by Ca²⁺ and the reaction is much slower and less efficient than vesicle fusion in a real synapse. One important additional protein

required for exocytosis of synaptic vesicles is Munc18 (mammalian unc18 homolog). Homologs of Munc18, referred to as SM proteins (sec1/Munc18-like proteins), are essential for intracellular fusion reactions in general. Munc18 binds to syntaxin before the SNARE complex assembles by an unknown mechanism. Deletion of Munc18 prevents all synaptic fusion in neurons. The core fusion machinery is thus composed of SNARE and SM proteins that are modulated by various accessory factors specific for particular fusion reactions.

After fusion, the SNARE complex must be disassembled for efficient vesicle recycling to occur. Rothman discovered that a cytoplasmic ATPase called NSF (*N*-ethylmaleimide-sensitive fusion protein) binds to SNARE complexes via an adaptor protein called

B SNARE complex

Figure 12–12 Formation and dissociation of the SNARE complex drives fusion of the synaptic vesicle and plasma membranes. (Adapted, with permission, from Rizo and Südhof 2002.)

A. The SNARE cycle. 1. Synaptobrevin interacts with two plasma membrane target proteins, the transmembrane protein syntaxin and the peripheral membrane protein SNAP-25. 2. The three proteins form a tight complex bringing the vesicle and presynaptic membranes in close apposition (see part B). Munc18 binds to the SNARE complex. 3. Calcium influx triggers rapid fusion of the vesicle and plasma membranes; the SNARE complex now resides in the plasma membrane. 4. Two proteins, NSF and SNAP (unrelated to SNAP-25), bind to the SNARE complex and cause it to dissociate in an ATP-dependent reaction.

B. The SNARE complex consists of a bundle of four α -helixes, one each from synaptobrevin and syntaxin and two from SNAP-25. The structure shown here is for the docked vesicle prior to fusion. The actual structure of the transmembrane domains has not been determined and is drawn here along with the vesicle and plasma membranes for illustrative purposes.

SNAP (soluble NSF-attachment protein, not related to the SNARE protein SNAP-25). NSF and SNAP use the energy of ATP hydrolysis to dissociate SNARE complexes, thereby regenerating free SNARE (Figure 12–12A). NSF also participates in the cycling of AMPA-type glutamate receptors in dendritic spines.

SNAP-25

Calcium Binding to Synaptotagmin Triggers Transmitter Release

Because fusion of synaptic vesicles with the plasma membrane must occur within a fraction of a millisecond, it is thought that most proteins responsible for fusion are assembled prior to Ca²⁺ influx. According to this view, once Ca²⁺ enters the presynaptic terminal it binds a Ca²⁺ sensor on the vesicle, triggering immediate fusion of the membranes.

A family of closely related synaptic vesicle proteins, the synaptotagmins, has been identified as the major Ca²⁺ sensors that trigger fusion. The synaptotagmins are membrane proteins with a single N-terminal transmembrane region that anchors them to the synaptic vesicle (Figure 12–13A). The cytoplasmic region of each synaptotagmin protein is largely composed of two domains, the C2 domains, which are a common protein motif homologous to the Ca²⁺ and phospholipid-binding C2 domain of protein kinase C. That the C2 domains bind not only Ca²⁺ but also phospholipids is consistent with their importance in calcium-dependent exocytosis. Moreover, the synaptotagmins bind Ca²⁺ over a concentration range similar to the Ca²⁺ concentration required to trigger transmitter release.

The two C2 domains bind a total of five Ca²⁺ ions, the same number of Ca²⁺ ions that electrophysiological experiments reveal are required to trigger release of a quantum of transmitter (Figure 12–13B). The binding of the Ca²⁺ ions to synaptotagmin is thought to act as a switch, promoting the interaction of the C2 domains with phospholipids. The C2 domains of synaptotagmin also interact with SNARE proteins, through both calcium-independent and calcium-dependent reactions.

Studies with mutant mice in which synaptotagmin 1 is deleted or its Ca²⁺ affinity is altered provide further evidence that synaptotagmin is the physiological Ca²⁺ sensor. When the affinity of synaptotagmin for Ca²⁺ is decreased twofold, the Ca²⁺ required for transmitter release is changed by the same amount. When synaptotagmin 1 is deleted in mice, flies, or worms, an action potential is no longer able to trigger fast synchronous release. However, Ca²⁺ is still capable of stimulating a slow form of release referred to as asynchronous release (Figure 12–13C). Thus, although synaptotagmin 1 is not required for all forms of calcium-mediated transmitter release, it is essential for fast synaptic transmission.

The Fusion Machinery Is Embedded in a Conserved Protein Scaffold at the Active Zone

A defining feature of fast synaptic transmission is that neurotransmitter is released by exocytosis at the active zone. Other types of exocytosis, such as that which occurs in the adrenal medulla, do not require a specialized domain of the plasma membrane. The active zone is thought to coordinate and regulate the docking and priming of synaptic vesicles to ensure the speed and tight regulation of release. This is accomplished

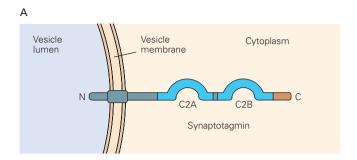

through a conserved set of proteins that form one large macromolecular structure.

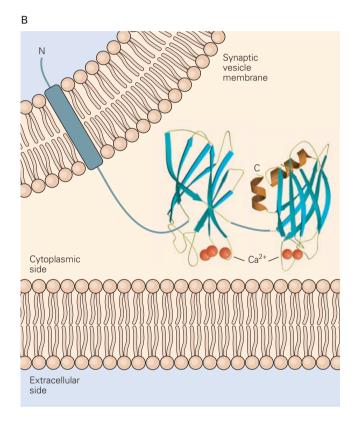

An exceedingly detailed view of the structure of the active zone at the frog neuromuscular junction has been obtained by Jack MacMahan using a powerful ultrastructural technique called scanning electron microscopic tomography. This technique has shown how synaptic vesicles are tethered to the membrane by a series of electron-dense projections, termed *ribs* and *beams*, that attach to defined sites on the vesicles and to particles (*pegs*) in the presynaptic membrane that may correspond to voltage-gated Ca²⁺ channels (Figure 12–14).

A key goal in understanding how the various synaptic vesicle and active zone proteins are coordinated during exocytosis is to fit the various proteins that have been identified into this high-resolution electron micrograph. Several cytoplasmic proteins have been identified that are thought to be components of a cytoskeletal matrix at the active zone. These include two large cytoplasmic multidomain proteins, Munc13 (not related to the Munc18 protein discussed above) and RIM, which form a tight complex with each other and may well comprise part of the ribs and beams. The binding of RIM and Munc13 is an important component of the priming of synaptic vesicles for exocytosis. Phosphorylation of RIM by cAMP-dependent protein kinase is likely to be a key regulatory mechanism in the long-term enhancement of transmitter release implicated in certain forms of learning and memory. As we will see below, regulation of Munc13 by second messengers is involved in short-term forms of synaptic plasticity. RIM binds several other synaptic vesicle proteins, including the Rab3 family of low molecular weight guanosine triphosphatases (GTPases). There are four Rab3 isoforms (Rab3A, B, C, and D) that transiently associate with synaptic vesicles as the GTP-Rab3 complex (Figure 12-11). The binding of RIM and Rab3 is thought to regulate the interaction of synaptic vesicles with the active zone during the vesicle cycle.

Modulation of Transmitter Release Underlies Synaptic Plasticity

The effectiveness of chemical synapses can be modified for short and long periods, a property called *synaptic plasticity*. Such functional modification can be effected by intrinsic or extrinsic signals. An example of an intrinsic signal is rapid firing; extrinsic signals include direct synaptic input from other neurons and more diffuse actions of neuromodulators.

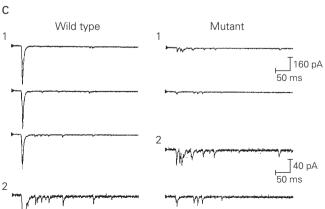

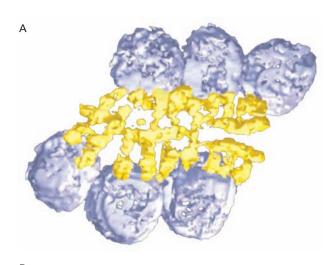

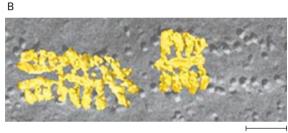

Figure 12–13 The structure of synaptotagmin and genetic evidence for its role in transmitter release.

A. Synaptotagmin is an integral membrane protein of synaptic vesicles. The short N-terminal tail, which resides in the vesicle lumen, is followed by a single hydrophobic domain that spans the vesicle membrane and a long cytoplasmic tail that contains two C2 domains (C2A and C2B) near the C terminus. The C2 domains are calcium- and phospholipid-binding motifs found in many other proteins, including PKC.

B. The X-ray crystal structure of the two C2 domains is shown here. The C2A domain binds three Ca²⁺ ions and the C2B domain two Ca²⁺ ions. The structures of the other regions of synaptotagmin have not yet been determined and are drawn here for illustrative purposes. The membrane and structures are drawn to scale.

C. Fast calcium-triggered transmitter release is absent in mutant mice lacking synaptotagmin. Recordings show excitatory postsynaptic currents evoked in vitro by stimulation of cultured hippocampal neurons from wild-type mice or mutant mice in which synaptotagmin has been deleted by homologous recombination (1). Neurons from wild-type mice show large, fast excitatory postsynaptic currents evoked by three successive presynaptic action potentials, reflecting the fact that synaptic transmission is dominated by the rapid synchronous release of transmitter from a large number of synaptic vesicles. In the bottom trace, where the synaptic current is shown at a highly expanded current scale (2), one can see that a small, prolonged phase of asynchronous release of transmitter follows the fast phase of synchronous release. During this slow phase there is a prolonged increase in frequency of individual quantal responses. In neurons from a mutant mouse a presynaptic action potential triggers only the slow asynchronous phase of release; the rapid synchronous phase has been abolished.

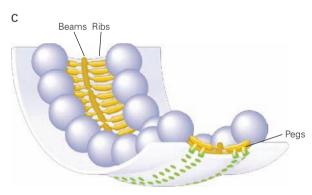

Figure 12–14 Synaptic vesicles at the active zone. The images are obtained from electron microscopic tomography. (Reproduced, with permission, from Harlow et al. 2001.)

A. Vesicles are tethered to filamentous proteins of the active zone. Three distinct filamentous structures are resolved: pegs, ribs, and beams. Ribs protruding from the vesicles are attached to long horizontal beams, which are anchored to the membrane by vertical pegs.

- **B.** Ribs and beams superimposed on a freeze fracture view of intramembranous particles at the active zone show how the ribs are aligned with the particles, some of which are presumed to be voltage-gated Ca²⁺ channels. Scale bar = 100 nm.
- **C.** A model for the structure of the active zone shows the relation between synaptic vesicles, pegs, ribs, and beams.

Synaptic strength can be modified presynaptically, by altering the release of neurotransmitter, or postsynaptically, by modulating the response to transmitter, or both. Long-term changes in presynaptic and postsynaptic mechanisms are crucial to development and learning (Chapters 66 and 67). Here we focus on how synaptic strength changes through modulation of the amount of transmitter released.

Transmitter release can be modulated dramatically and rapidly—by several-fold in a matter of seconds—and this change can be maintained for seconds, to hours, or even days. In principle, such changes can be mediated by two different mechanisms: changes in Ca²⁺ influx or changes in the amount of transmitter released in response to a given Ca²⁺ concentration.

Synaptic strength commonly is enhanced by intense activity. In many neurons a high-frequency train of action potentials is followed by a period during which a single action potential produces successively larger postsynaptic potentials (Figure 12–15A). High-frequency stimulation of the presynaptic neuron, which in some cells can generate 500 to 1,000 action potentials per second, is called *tetanic stimulation*. The increase in size of the EPSP during tetanic stimulation is called potentiation; the increase that persists after tetanic stimulation is called post-tetanic potentiation (Figure 12–15A). This enhancement usually lasts several minutes, but it can persist for an hour or more at some synapses. The opposite effect, a decrease in the size of postsynaptic potentials, occurs in response to more prolonged periods of high-frequency stimulation. This effect is referred to as synaptic *depression* (Figure 12-15B).

Activity-Dependent Changes in Intracellular Free Calcium Can Produce Long-Lasting Changes in Release

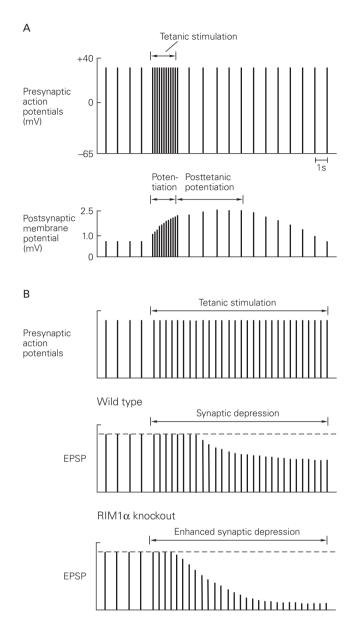

Because transmitter release depends strongly on the intracellular Ca²⁺ concentration, mechanisms that affect the concentration of free Ca²⁺ in the presynaptic terminal also affect the amount of transmitter released. Normally the rise in Ca²⁺ in the presynaptic terminal in response to an action potential is rapidly buffered by cytoplasmic calcium-binding proteins and mitochondria; Ca²⁺ is also actively transported out of the neuron by pumps and transporters.

However, during tetanic stimulation so much Ca²⁺ flows into the axon terminals that the Ca²⁺ buffering and clearance systems become saturated. This leads to a temporary excess of Ca²⁺, called *residual* Ca²⁺. The residual free Ca²⁺ enhances synaptic transmission for many minutes or longer by activating certain enzymes

Figure 12–15 Repetitive presynaptic firing produces persistent changes in transmitter release.

A. A brief burst of high-frequency stimulation leads to a sustained enhancement in transmitter release. The time scale of the experimental records here has been compressed (each presynaptic and postsynaptic potential appears as a simple line indicating its amplitude). A stable excitatory postsynaptic potential (EPSP) of around one mV is produced when the presynaptic neuron is stimulated at a relatively low rate of one action potential per second. The presynaptic neuron is then stimulated for a few seconds at a higher rate of 50 action potentials per second. During this tetanic stimulation the EPSP increases in size because of enhanced release, a phenomenon known as potentiation. After several seconds of stimulation. the presynaptic neuron is returned to the initial rate of stimulation (1 per second). However, the EPSPs remain enhanced for minutes, and in some cells for several hours. This persistent increase is called posttetanic potentiation.

B. Prolonged tetanic stimulation can decrease the amplitude of the EPSP, a phenomenon called *synaptic depression*. In this example the presynaptic neuron produces a stable postsynaptic response of 1 mV when stimulated at a rate of 1 action potential per second. When the rate of stimulation is increased to 15 action potentials per second, the EPSP eventually declines in amplitude. This synaptic depression is thought to result from the temporary depletion of the store of releasable synaptic vesicles. Deletion of the active zone protein RIM1 α enhances synaptic depression. (Adapted, with permission, from Schoch et al. 2002.)

that are sensitive to enhanced levels of resting Ca²⁺, such as, the Ca²⁺/calmodulin-dependent protein kinase. Activation of such calcium-dependent enzymatic pathways is thought to increase the priming of synaptic vesicles in the terminals.

Here then is the simplest kind of cellular memory! The presynaptic cell stores information about the history of its activity in the form of residual Ca²⁺ in its terminals. This Ca²⁺ acts by multiple pathways that have different halftimes of decay. In Chapters 66 and 67 we shall see how posttetanic potentiation at certain synapses is followed by an even longer-lasting process (also initiated by Ca²⁺ influx), called *long-term potentiation*, which can last for many hours or even days.

During prolonged tetanic stimulation synaptic vesicles become depleted at the active zone, resulting in synaptic depression. To counteract this depression, the synapse utilizes multiple mechanisms that often involve a complex of two of the active zone proteins discussed above, Munc13 and RIM. For example, prolonged tetanic stimulation activates phospholipase C, which produces inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol. Diacylglycerol directly interacts with a protein domain on Munc13 called the C1 domain (no relation to the C2 domain) homologous to the diacylglycerol-binding domain in protein kinase C. Binding of diacylglycerol to Munc13 during prolonged repetitive stimulation helps maintain a high rate of transmitter

release even in the face of depression by accelerating the rate of synaptic vesicle recycling. As a result, deletion of Munc13 or RIM results, among other actions, in an enhancement in depression (Figure 12–15B).

Axo-axonic Synapses on Presynaptic Terminals Regulate Transmitter Release

Synapses are formed on axon terminals as well as the cell body and dendrites of neurons (see Chapter 10). Although axosomatic synaptic actions affect all branches of the postsynaptic neuron's axon (because they affect the probability that the neuron will fire an action potential), axo-axonic actions selectively control individual terminals of the axon. One important action of axo-axonic synapses is to increase or decrease Ca²⁺ influx into the presynaptic terminals of the postsynaptic cell, thereby enhancing or depressing transmitter release, respectively.

As we saw in Chapter 10, when one neuron releases transmitter that hyperpolarizes the cell body (or dendrites) of another, it decreases the likelihood that the postsynaptic cell will fire; this action is called postsynaptic inhibition. In contrast, when a neuron makes synapses onto the axon terminal of another cell, it can reduce the amount of transmitter that will be released by the postsynaptic cell onto a third cell; this action is called presynaptic inhibition (Figure 12-16A). Other axo-axonic synaptic actions can increase the amount of transmitter released by the postsynaptic cell; this action is called presynaptic facilitation (Figure 12–16B). Both presynaptic inhibition and facilitation can occur in response to activation of ionotropic or metabotropic receptors in the membrane of the presynaptic terminals. For reasons that are not well understood, presynaptic modulation usually occurs early in sensory pathways.

The best-analyzed mechanisms of presynaptic inhibition and facilitation are in invertebrate neurons and vertebrate mechanoreceptor neurons (whose cell bodies lie in dorsal root ganglia). Three mechanisms for presynaptic inhibition have been identified in these cells. One mechanism depends on the activation of ionotropic GABA receptor-channels in the presynaptic terminal. The opening of these channels leads to an increased conductance to Cl⁻, which decreases (or short-circuits) the amplitude of the action potential in the presynaptic terminal. The smaller depolarization activates fewer Ca²⁺ channels, thereby decreasing transmitter release.

The other two mechanisms both result from the activation of presynaptic G protein-coupled metabotropic receptors. One type of action results from the modulation of ion channels. As we saw in Chapter 11, the $\beta\gamma$ -subunit complex of G proteins can simultaneously close voltage-gated Ca²⁺ channels and open K⁺

channels. This decreases the influx of Ca^{2+} and enhances repolarization of the presynaptic terminal, thus diminishing transmitter release. The second type of G protein-dependent action depends on a direct action by the $\beta\gamma$ -subunit complex on the release machinery itself, independent of any changes in ion channel activity or Ca^{2+} influx. This second action is thought to involve a decrease in the Ca^{2+} sensitivity of the release machinery.

In contrast, presynaptic facilitation can be caused by enhanced influx of Ca²⁺. In certain molluscan neurons serotonin acts through cAMP-dependent protein phosphorylation to close K⁺ channels in the presynaptic terminal (including the Aplysia S-type K+ channel discussed in Chapter 11). This action increases the duration of the presynaptic action potential, thereby increasing Ca2+ influx by enabling the voltage-dependent Ca²⁺ channels to remain open for a longer period. In other cells activation of presynaptic ionotropic receptors increases transmitter release. This facilitation can be caused directly in the case of Ca²⁺-permeable receptor-channels by directly enhancing Ca2+ influx, or indirectly in the case of voltage-gated Ca2+ channels through depolarization of the presynaptic terminal, which leads to increased Ca²⁺ influx.

Thus, presynaptic terminals are endowed with a variety of mechanisms that allow for the fine-tuning of the strength of synaptic transmission. Although we know a fair amount about short-term changes in synaptic strength—changes that last minutes and hours—we are only beginning to learn about mechanisms that support changes that persist for days, weeks, and longer. These long-term changes often require alterations in gene expression and growth of presynaptic and postsynaptic structures in addition to alterations in Ca²⁺ influx and enhancement of transmitter release from existing terminals.

An Overall View

In his book *Ionic Channels of Excitable Membranes*, Bertil Hille summarizes the importance of calcium in neuronal function as follows:

Electricity is used to gate channels and channels are used to make electricity. However, the nervous system is not primarily an electrical device. Most excitable cells ultimately translate their electrical excitation into another form of activity. As a broad generalization, excitable cells translate their electricity into action by Ca²⁺ fluxes modulated by voltage-sensitive Ca²⁺ channels. Calcium ions are intracellular messengers capable of activating many cell functions. Calcium channels... serve as the only link to transduce depolarization into all the non-electrical activities controlled by excitation. Without Ca²⁺ channels our nervous system would have no outputs.

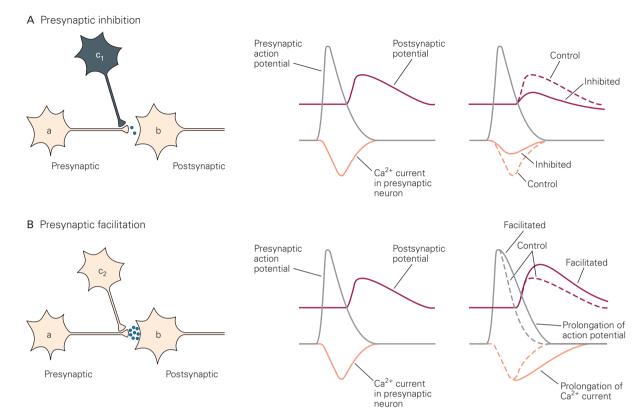

Figure 12–16 Axoaxonic synapses can inhibit or facilitate transmitter release by the presynaptic cell.

A. An inhibitory neuron (c₁) forms a synapse on the axon terminal of neuron a. Release of transmitter by cell c₁ activates a metabotropic receptor on the terminals of cell a, which inhibits the Ca²⁺ current in these terminals, thereby reducing the amount of transmitter released by cell a onto cell b. The reduction of transmitter release from cell a in turn reduces the amplitude of the excitatory postsynaptic potential in cell b, a process termed presynaptic inhibition.

B. A facilitating neuron (c_2) forms a synapse on the axon terminal of neuron a. Release of transmitter by cell c_2 activates a metabotropic receptor on the terminals of cell a, which decreases a K⁺ current in the terminals, thereby prolonging the action potential and increasing Ca^{2+} influx into cell a. This increases transmitter release from cell a onto cell b, thereby increasing the size of the EPSP in cell b, a process termed presynaptic facilitation.

Neither Na⁺ influx nor K⁺ efflux is required to release neurotransmitter at a synapse. Only Ca²⁺, which enters the cell through voltage-gated channels in the presynaptic terminal, is essential. Synaptic delay—the time between the onset of the action potential and the release of transmitter—largely reflects the time it takes for voltage-gated Ca²⁺ channels to open and for Ca²⁺ to trigger the discharge of transmitter from synaptic vesicles.

Transmitter is packaged in vesicles that each contain approximately 5,000 transmitter molecules. The all-or-none release of transmitter from a single vesicle results in a quantal synaptic potential. Synaptic potentials evoked by nerve stimulation are comprised of integral multiples of the quantal potential caused by the release of transmitter from multiple synaptic vesicles.

Increasing the extracellular Ca²⁺ does not change the size of the quantal synaptic potential. Rather, it increases the probability that a vesicle will discharge its transmitter. As a result, the number of vesicles that release transmitter is increased, leading to a larger postsynaptic potential. In addition, transmitter is spontaneously released at low rates from synaptic vesicles, producing what are called *spontaneous miniature synaptic potentials*.

Electron microscopic images of presynaptic terminals that have been rapidly frozen following electrical stimulation reveal that synaptic vesicles release transmitter by exocytosis. The vesicle membrane fuses with the plasma membrane in the vicinity of the active zone, allowing the transmitter to flow out of the cell toward receptors on a postsynaptic cell. A conserved protein

machinery mediates the exocytosis and rapid retrieval of synaptic vesicles that allows nerve terminals to maintain a high rate of transmitter release, even during prolonged trains of action potentials.

Vesicle fusion is thought to be catalyzed by the assembly of a synaptic vesicle SNARE protein (v-SNARE) with a pair of SNARE proteins in the presynaptic target membrane (t-SNARES) into a tight complex that forces the synaptic vesicle and plasma membrane into close proximity. Two other proteins, Munc13 and Munc18, are essential for synaptic vesicle fusion, probably because they enable SNARE complex assembly. Calcium triggers the opening of the vesicles during a late step in the synaptic vesicle cycle by binding to synaptotagmin, a synaptic vesicle protein that serves as the major Ca²⁺ sensor in exocytosis. The machinery that executes fusion and Ca2+ triggering is embedded in the active zone by a conserved protein scaffold that also regulates transmitter release. A critical component of this scaffold is a large multidomain protein called RIM that binds to Rab3, a GTP-binding protein on synaptic vesicles, and also interacts with Munc13.

The amount of transmitter released from a neuron is not fixed but can be modified by both intrinsic and extrinsic modulatory processes. High-frequency stimulation produces an increase in transmitter release called posttetanic potentiation. This potentiation, which lasts a few minutes, is caused by an action of the residual Ca²⁺ remaining in the terminal after the large Ca²⁺ signal that occurs during the train of action potentials has been largely dissipated by diffusion, buffering, and extrusion. Neurotransmitters acting at axo-axonic synapses can facilitate or inhibit release of transmitter by altering the steady-state level of resting Ca²⁺, the Ca²⁺ influx during the action potential, or the functioning of the release machinery.

Small-Molecule Transmitters Are Actively Taken Up into Vesicles

Many Neuroactive Peptides Serve as Transmitters

Peptides and Small-Molecule Transmitters Differ in Several Ways

Peptides and Small-Molecule Transmitters Coexist and Can Be Co-released

Removal of Transmitter from the Synaptic Cleft Terminates Synaptic Transmission

An Overall View

HEMICAL SYNAPTIC TRANSMISSION can be divided into four steps—(1) synthesis and storage of a transmitter substance, (2) release of the transmitter, (3) interaction of the transmitter with receptors at the postsynaptic membrane, and (4) removal of the transmitter from the synaptic cleft. In the previous chapter we considered steps 2 and 3: the release of transmitters and how they interact with postsynaptic receptors. We now turn to the initial and final steps of

chemical synaptic transmission: the synthesis of transmitter molecules and their removal from the synaptic cleft after synaptic action.

A Chemical Messenger Must Meet Four Criteria to Be Considered a Neurotransmitter

Before considering the biochemical processes involved in synaptic transmission, it is important to make clear what is meant by a chemical transmitter. The concept is empirical rather than logical and has changed over the years with increased understanding of synaptic transmission.

The concept that nerve stimulation led to release of chemical signals was elaborated as early as 1905 by the physiologist John Newport Langley, who demonstrated that adrenomedullary extracts elicited tissue responses comparable to sympathetic nerve stimulation. However, Thomas Renton Elliott is generally credited with the first experimental evidence of chemical neurotransmission in his observations that the physiological effects of sympathetic nerve stimulation were due to release of adrenaline. In 1921 Otto Loewi demonstrated the release of acetylcholine (ACh) from vagus nerve terminals in frog hearts. Henry Dale extended Loewi's work on ACh, later sharing the Nobel Prize with Loewi. In 1946 Ulf von Euler reported further work on adrenergic transmission. The terms cholinergic and adrenergic were introduced to indicate that a neuron makes and releases ACh or norepinephrine (or epinephrine), the two substances first recognized as neurotransmitters.

Since that time many other substances have been identified as transmitters. Furthermore, because of the

work of Bernard Katz in the 1950s on quantal release (see Chapter 12), it is usually taken for granted that substances acting as transmitters are stored in vesicles at synapses and released by exocytosis. Nevertheless some substances considered to be neurotransmitters are released into the synaptic cleft directly from the cytoplasm as well as by exocytosis. Thus ideas about neurotransmitters have had to be modified continually to accommodate new information about the cell biology of neurons and the pharmacology of receptors.

As a first approximation, a neurotransmitter can be defined as a substance that is released by a neuron and that affects a specific target in a specific manner. A target can be either another neuron or an effector organ, such as muscle or gland. As with many other operational concepts in biology, the concept of a transmitter is not precise. Neurotransmitters are protean, resembling other released agents in many regards yet also differing from them depending on the site of action and circumstances. Although the actions of hormones and neurotransmitters are quite similar, neurotransmitters usually act on targets that are close to the site of transmitter release, whereas hormones are released into the bloodstream to act on distant targets.

Neurotransmitters differ from autacoids in that a transmitter typically acts on a target other than the releasing neuron itself, whereas an autacoid acts only on the cell from which it was released. Nevertheless, at some synapses transmitters activate not only receptors in the postsynaptic cell but also autoreceptors on the presynaptic terminal. Autoreceptors usually modulate synaptic transmission that is in progress, for example, by limiting further release of transmitter or inhibiting subsequent transmitter synthesis. Receptors can also exist on presynaptic terminals at axo-axonic synapses, where the presynaptic terminal receives synaptic input from another neuron. These receptors function as heteroreceptors that regulate terminal excitability and transmitter release (see Chapter 12).

Importantly, the interaction of neurotransmitters with receptors is typically transient, lasting from milliseconds to minutes. Nevertheless, neurotransmitter action can result in long-term changes within target cells lasting hours or days. Lastly, increasing evidence suggests that a non-neural cell, the astrocyte, can also synthesize, store, and release neurotransmitters as well as express receptors that modulate astrocyte function.

Despite these difficulties in arriving at a strict definition, a limited number of substances of low molecular weight are generally accepted as neurotransmitters. Even so, it is often difficult to demonstrate that a specific transmitter operates at a particular synapse, particularly given the diffusibility and rapid reuptake or degradation of transmitters at the synaptic cleft. Because of this difficulty, many neurobiologists believe that a substance should not be accepted as a neurotransmitter unless the following four criteria are met:

- 1. It is synthesized in the presynaptic neuron.
- 2. It is present in the presynaptic terminal and is released in amounts sufficient to exert a defined action on the postsynaptic neuron or effector organ.
- 3. When administered exogenously in reasonable concentrations it mimics the action of the endogenous transmitter (for example, it activates the same ion channels or second-messenger pathway in the postsynaptic cell).
- 4. A specific mechanism usually exists for removing the substance from the synaptic cleft.

The nervous system makes use of two main classes of chemical substances for signaling: small-molecule transmitters and neuroactive peptides, which are short polymers of amino acids. Both classes of neurotransmitters are contained in vesicles, large and small. Neuropeptides are packaged in large dense-core vesicles (approximately 70–250 nm in diameter), which release their contents by exocytosis, similar to those seen in secretory glands and mast cells. Small-molecule transmitters are packaged in small electron-lucent vesicles (~40 nm in diameter), which release their contents through exocytosis at active zones closely associated with specific Ca²⁺ channels (see Chapter 12). Large dense-core vesicles can contain both small-molecule transmitters and neuropeptides.

Both types of vesicles are found in most neurons but in different proportions. Small synaptic vesicles are characteristic of neurons that use ACh, glutamate, γ-aminobutyric acid (GABA), and glycine as transmitters, whereas large dense-core vesicles are typical of neurons that use catecholamines and serotonin as transmitters. The adrenal medulla, once used as a model for studying exocytosis, contains only secretory granules that are similar to large dense-core vesicles. Because dense-core vesicles can contain both small-molecule transmitters and neuropeptides, they are important in co-transmission, which is discussed later in this chapter.

Only a Few Small-Molecule Substances Act as Transmitters

A relatively small number of low-molecular-weight substances are generally accepted as neurotransmitters, including ACh, amino acids or their amine-containing derivatives, adenosine triphosphate (ATP), and ATP

Table 13–1 Small-Molecule Transmitter Substances and Their Precursors

Transmitter	Precursor
Acetylcholine	Choline
Biogenic amines Dopamine Norepinephrine Epinephrine Serotonin Histamine Melatonin	Tyrosine Tyrosine Tyrosine Tryptophan Histidine Serotonin
Amino acids Aspartate γ-Aminobutyric acid Glutamate Glycine	Oxaloacetate Glutamine Glutamine Serine

metabolites (Table 13–1). The amine chemical messengers share many biochemical similarities. All are charged small molecules that are formed in relatively short biosynthetic pathways and synthesized either from essential amino acids or from precursors derived from the major carbohydrate substrates of intermediary metabolism. Like other pathways of intermediary metabolism, synthesis of these neurotransmitters is catalyzed by enzymes that, almost without exception, are cytosolic. ATP, which originates in mitochondria, is abundantly present throughout the cell.

As in any biosynthetic pathway, the overall synthesis of amine transmitters typically is regulated at one rate-limiting enzymatic reaction. The rate-limiting step often is characteristic of one type of neuron and usually is absent in other types of mature neurons.

Acetylcholine

Acetylcholine is the only low-molecular-weight amine transmitter substance that is not an amino acid or derived directly from one. The biosynthetic pathway for ACh has only one enzymatic reaction, catalyzed by choline acetyltransferase (step 1 in the reaction shown

below). This transferase is the characteristic and limiting enzyme in ACh biosynthesis. Nervous tissue cannot synthesize choline, which is derived from the diet and delivered to neurons through the blood stream. The co-substrate, acetyl coenzyme A (acetyl CoA), participates in many general metabolic pathways and is not restricted to cholinergic neurons.

Acetyl CoA + choline

(1)

O

$$CH_3 - C - O - CH_2 - CH_2 - N - (CH_3)_3 + CoA$$

Acetylcholine

Acetylcholine is released at all vertebrate neuromuscular junctions by spinal motor neurons (see Chapter 9). In the autonomic nervous system it is the transmitter for all preganglionic neurons and for parasympathetic postganglionic neurons as well (see Chapter 47). Cholinergic neurons form synapses throughout the brain; those in the nucleus basalis have particularly widespread projections to the cerebral cortex. Acetylcholine (together with a noradrenergic component) is a principle neurotransmitter of the reticular activating system, which modulates arousal, sleep, wakefulness, and other critical aspects of human consciousness.

Biogenic Amine Transmitters

The term *biogenic amine*, although chemically imprecise, has been used for decades to designate certain neurotransmitters. This group includes the catecholamines and serotonin. Histamine, an imidazole, is also often referred to as a biogenic amine, although its biochemistry is remote from the catecholamines and the indolamines.

Catecholamine Transmitters

The catecholamine transmitters—dopamine, norepine-phrine, and epinephrine—are all synthesized from the essential amino acid tyrosine in a common biosynthetic pathway containing five enzymes: tyrosine hydroxylase, pteridine reductase, aromatic amino acid decarboxylase, dopamine β -hydroxylase, and phenylethanolamine-N-methyl transferase. Catecholamines have the catechol nucleus, a 3,4-dihydroxylated benzene ring.

The first enzyme, tyrosine hydroxylase (step 1 below), is an oxidase that converts tyrosine to L-dihydroxyphenylalanine (L-DOPA). This enzyme is rate-limiting for the synthesis of both dopamine and norepinephrine. It is present in all cells producing

catecholamines and requires a reduced pteridine cofactor, Pt-2H, which is regenerated from pteridine (Pt) by another enzyme, pteridine reductase, which uses nicotinamide adenine dinucleotide (NADH) (step 4 below). This reductase is not specific to neurons.

Tyrosine +
$$O_2$$

Pt-2H

Pt

 $CH_$

L-DOPA is next decarboxylated by aromatic amino acid decarboxylase, also called L-DOPA decarboxylase (step 2 below), to yield dopamine and CO₂:

L-DOPA
$$(2)$$
 HO $CH_2-CH_2-NH_2+CO_2$

The third enzyme in the sequence, dopamine β -hydroxylase (step 3 below), converts dopamine to norepinephrine. Unlike all other enzymes in the biosynthetic pathways of small-molecule neurotransmitters, dopamine β -hydroxylase is membrane-associated. It is bound tightly to the inner surface of aminergic vesicles as a peripheral protein. Consequently, norepinephrine is the only transmitter synthesized within vesicles.

In the central nervous system norepinephrine is used as a transmitter by neurons with cell bodies in the locus ceruleus, a nucleus of the brain stem with many complex modulatory functions (see Chapter 46). Although these adrenergic neurons are relatively few in number, they project diffusely throughout the cortex, cerebellum, and spinal cord. In the peripheral nervous system norepinephrine is the transmitter of the postganglionic neurons in the sympathetic nervous system (see Chapter 47).

In addition to these four catecholaminergic biosynthetic enzymes, a fifth enzyme, phenylethanolamine-*N*-methyltransferase (step 5 below), methylates norepinephrine to form epinephrine (adrenaline) in the

adrenal medulla. This reaction requires *S*-adenosylmethionine as a methyl donor. The transferase is a cytoplasmic enzyme. Thus, for epinephrine to be formed, its immediate precursor, norepinephrine, must exit from vesicles into the cytoplasm. For epinephrine to be released, it must then be taken up into vesicles. Only a small number of neurons in the brain use epinephrine as transmitter.

Norepinephrine
$$(5)$$
 HO CH_2 CH_2 CH_2 $NH - CH_3$ Epinephrine

The production of these catecholamine neurotransmitters is controlled by feedback regulation of the first enzyme in the pathway. Not all cells that release catecholamines express all five biosynthetic enzymes, although cells that release epinephrine do. During development the expression of the genes encoding these synthetic enzymes is independently regulated and the particular catecholamine produced by a cell is determined by which enzyme(s) in the step-wise pathway are not expressed. Thus, neurons that release norepinephrine do not express the methyltransferase, and neurons that release dopamine do not express the transferase or dopamine β -hydroxylase.

Of the four major dopaminergic nerve tracts, three arise in the midbrain (see Chapter 46). Dopaminergic neurons in the substantia nigra that project to the striatum are important for the control of movement and are affected in Parkinson disease and other disorders of movement. The mesolimbic and mesocortical tracts are critical for affect, emotion, attention, and motivation and are implicated in schizophrenia and drug addiction (see Chapters 48, 49, and 62). A fourth dopaminergic tract, the tuberoinfundibular pathway, originates in the arcuate nucleus of the hypothalamus and projects to the pituitary gland, where it regulates secretion of hormones (see Chapter 46).

The synthesis of biogenic amines is highly regulated and can be rapidly increased. As a result, the amounts of transmitter available for release can keep up with wide variations in neuronal activity. Opportunities for regulating both the synthesis of catecholamine transmitters and the production of enzymes in the stepwise catecholamine pathway are discussed in Box 13–1.

Trace amines, naturally occurring catecholamine derivatives, may also be transmitters. In invertebrates the tyrosine derivatives tyramine and octopamine play key roles in numerous physiological processes

Box 13–1 Catecholamine Production Varies with Neuronal Activity

The production of norepinephrine is able to keep up with wide variations in neuronal activity because it is highly regulated. In autonomic ganglia the amount of norepinephrine is regulated transsynaptically. Activity in the presynaptic neurons, which are both cholinergic and peptidergic, first induces short-term changes in second messengers in the postsynaptic adrenergic cells.

These changes increase the supply of norepinephrine through the cAMP-dependent phosphorylation of tyrosine hydroxylase, the first enzyme in the norepinephrine biosynthetic pathway. Phosphorylation enhances the affinity of the hydroxylase for the pteridine cofactor and diminishes feedback inhibition by end products such as norepinephrine. Phosphorylation of tyrosine hydroxylase lasts only as long as cAMP remains elevated, as the phosphorylated hydroxylase is quickly dephosphorylated by protein phosphatases.

If presynaptic activity is sufficiently prolonged, however, other changes in the production of norepine-phrine will occur. Severe stress to an animal results in intense presynaptic activity and persistent firing of the postsynaptic adrenergic neuron, placing a greater demand on transmitter synthesis. To meet this challenge, the tyrosine hydroxylase gene is induced to increase production of the enzyme protein. Elevated amounts of tyrosine hydroxylase are observed in the cell body within hours after stimulation and at nerve endings days later.

This induction of increased levels of tyrosine hydroxylase begins with the persistent release of chemical transmitters from the presynaptic neurons and prolonged activation of the cAMP pathway in postsynaptic adrenergic cells, which activates the cAMP-dependent protein kinase (PKA). This kinase phosphorylates not only existing tyrosine hydroxylase molecules, but also a transcription factor, cAMP response element binding protein (CREB).

Once phosphorylated, CREB binds a specific DNA enhancer sequence called the cAMP-recognition element (CRE), which lies upstream (5') of the gene for the hydroxylase. Binding of CREB to CRE facilitates the binding of RNA polymerase to the gene's promoter, increasing tyrosine hydroxylase transcription. Induction of tyrosine hydroxylase was the first known example of a neurotransmitter altering gene expression.

There is a high degree of similarity in amino acid and nucleic acid sequences encoding three of the biosynthetic enzymes: tyrosine hydroxylase, dopamine β -hydroxylase, and phenylethanolamine-N-methyltransferase. This similarity suggests that the three enzymes arose from a common ancestral protein.

Moreover, long-term changes in the synthesis of these enzymes are coordinately regulated in adrenergic neurons. At first, this discovery suggested that the genes encoding these enzymes might be located sequentially along the same chromosome and be controlled by the same promoter, like genes in a bacterial operon. But in humans the genes for the biosynthetic enzymes for nore-pinephrine are not located on the same chromosome. Therefore, coordinate regulation is likely achieved by parallel activation through similar but independent transcription activator systems.

including behavioral regulation. Trace amine receptors also have been identified in mammals, where their function is still a matter of some controversy.

Serotonin

Serotonin (5-hydroxytryptamine or 5-HT) and the essential amino acid tryptophan from which it is derived belong to a group of aromatic compounds called indoles, with a five-member ring containing nitrogen joined to a benzene ring. Two enzymes are needed to synthesize serotonin: tryptophan (Trp) hydroxylase (step 1 in the following reaction), an oxidase similar to tyrosine hydroxylase, and aromatic amino acid decarboxylase, also called 5-hydroxytryptophan (5-HTP) decarboxylase (step 2 in the following reaction).

Try
$$(1)$$
 5-HTP (2) (2) (2) (2) (2) (2) (2) (2) (2) (2) (3) (3) (4)

The limiting reaction is catalyzed by the first enzyme in the pathway, tryptophan hydroxylase. Tryptophan hydroxylase is similar to tyrosine hydroxylase not only in catalytic mechanism but also in amino acid sequence. The two enzymes are thought to stem from a common ancestral protein by gene duplication because the two hydroxylases are syntenic, that is, they are encoded by genes close together on the same chromosome (tryptophan hydroxylase, 11p15.3-p14;

tyrosine hydroxylase, 11p15.5). The second enzyme in the pathway, 5-hydroxytryptophan decarboxylase, is identical to L-DOPA decarboxylase. Enzymes with similar activity, L-aromatic amino acid decarboxylases, are present in non-nervous tissues as well.

The cell bodies of serotonergic neurons are found in and around the midline raphe nuclei of the brain stem and are involved in regulating attention and other complex cognitive functions (Chapter 46). The projections of these cells (like those of noradrenergic cells in the locus ceruleus) are widely distributed throughout the brain and spinal cord. Serotonin and the catecholamines norepinephrine and dopamine are implicated in depression, a major mood disorder. Antidepressant medications inhibit the uptake of serotonin, norepinephrine, and dopamine, thereby increasing the magnitude and duration of the action of these transmitters, which in turn leads to altered cell signaling and adaptations (see Chapter 63).

Histamine

Histamine, derived from the essential amino acid histidine by decarboxylation, contains a characteristic five-member ring with two nitrogen atoms. It has long been recognized as an autacoid, active when released from mast cells in the inflammatory reaction and in the control of vasculature, smooth muscle, and exocrine glands (eg, secretion of highly acidic gastric juice). Histamine is a transmitter in both invertebrates and vertebrates. It is concentrated in the hypothalamus, one of the centers for regulating the secretion of hormones (see Chapter 47). The decarboxylase catalyzing its synthesis (step 1 below), although not extensively analyzed, appears to be characteristic of histaminergic neurons.

Amino Acid Transmitters

In contrast to acetylcholine and the biogenic amines, which are not intermediates in general metabolic pathways and are produced only in certain neurons, the amino acids glutamate and glycine are not only neurotransmitters but also universal cellular constituents. Because they can be synthesized in neurons, neither are essential amino acids.

Glutamate, the neurotransmitter most frequently used at excitatory synapses throughout the central

nervous system, is produced from α -ketoglutarate, an intermediate in the tricarboxylic acid cycle of intermediary metabolism. After it is released, glutamate is taken up from the synaptic cleft by specific transporters in the membrane of both neurons and glia (see below). The glutamate taken up by astrocytes is converted to glutamine by the enzyme glutamine synthase. This glutamine then diffuses back into neurons that use glutamate as a transmitter, where it is hydrolyzed back to glutamate. Phosphate-activated glutaminase (PAG), which is present at high concentrations in these neurons, is responsible for salvaging the molecule for reuse as a transmitter.

Glycine is the major transmitter used by inhibitory interneurons of the spinal cord. It is also an allosteric modulator of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors (see Chapter 10). Glycine is synthesized from serine. Its specific biosynthesis in neurons is not well understood, but its biosynthetic pathway in other tissues is well known. The amino acid GABA is synthesized from glutamate in a reaction catalyzed by glutamic acid decarboxylase (step 1 below):

GABA is present at high concentrations throughout the central nervous system and is also detectable in other tissues. It is used as a transmitter by an important class of inhibitory interneurons in the spinal cord. In the brain GABA is the major transmitter of various inhibitory neurons and interneurons, such as the medium spiny neurons of the striatum, striatal interneurons, basket cells of both the cerebellum and the hippocampus, the Purkinje cells of the cerebellum, granule cells of the olfactory bulb, and amacrine cells of the retina.

ATP and Adenosine

ATP and its degradation products (eg, adenosine) act as transmitters at some synapses. Adenosine has an inhibitory effect through a number of adenosine receptors in the central nervous system and caffeine's stimulatory effects depend on inhibition of adenosine binding to its receptors. Adenine and guanine and

their sugar-containing derivatives are called purines; the evidence for transmission at purinergic receptors is especially strong for autonomic neurons that innervate the vas deferens, bladder, and muscle fibers of the heart; for nerve plexuses on smooth muscle in the gut; and for some neurons in the brain. Purinergic transmission is particularly important for nerves mediating pain (see Chapter 22).

ATP released by tissue damage acts to transmit pain sensation through one type of ionotropic purine receptor present on the terminals of peripheral axons of nociceptor dorsal root ganglion cells. ATP released from terminals of the central axons of the dorsal root ganglion cells excites another type of ionotropic purine receptor on neurons in the dorsal horn of the spinal cord.

Small-Molecule Transmitters Are Actively Taken Up into Vesicles

Common amino acids act as transmitters in some neurons but not in others, indicating that the presence of a substance in a neuron, even in substantial amounts, is not in itself sufficient evidence that the substance is used as a transmitter. For example, at the neuromuscular junction of the lobster (and other arthropods) GABA is inhibitory and glutamate is excitatory. The concentration of GABA is approximately 20 times greater in inhibitory cells than in excitatory cells, supporting the idea that GABA is the inhibitory transmitter at the lobster neuromuscular junction. In contrast, the concentration of the excitatory transmitter, glutamate, is similar in both excitatory and inhibitory cells. Glutamate therefore must be compartmentalized within these neurons; that is, transmitter glutamate must be kept separate from metabolic glutamate. In fact, transmitter glutamate is compartmentalized in synaptic vesicles.

Although the presence of a specific set of biosynthetic enzymes can determine whether a small molecule can be used as a transmitter, it does not mean that the molecule will be used. Before a substance can be released as a transmitter it usually must first be concentrated in synaptic vesicles. Transmitter concentrations within vesicles are high, on the order of several hundred millimolar. Neurotransmitter substances are concentrated in vesicles by transporters that are specific to each type of neuron and energized by a vacuolar-type H⁺-ATPase (V-ATPase) common to neurons of all types (and found also in glandular tissue, such as the adrenal medulla).

Using the energy generated by the hydrolysis of cytoplasmic ATP, the V-ATPase creates a $H^{\scriptscriptstyle +}$ electro-

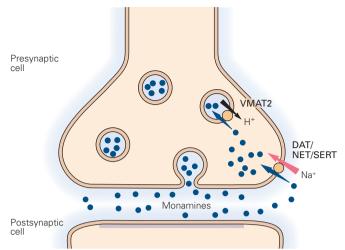

chemical gradient by promoting the influx of protons into the vesicle. Transporters use this proton gradient to drive transmitter molecules into the vesicles against their concentration gradient. A number of different vesicular transporters have been identified in mammals that are responsible for concentrating different transmitter molecules in vesicles (Figure 13–1). These proteins span the vesicle membrane 12 times, and are distantly related to a class of bacterial transporters that mediate drug-resistance. (Although related in function, vesicular transporters differ structurally and mechanistically from the transporters in the plasma membrane, which are driven by the Na⁺ electrochemical gradient rather than by H⁺. See below.)

Transmitter molecules are taken up into a vesicle by vesicular transporters in exchange for the transport of two protons out of the vesicle. Because the maintenance of the pH gradient requires the hydrolysis of ATP, the uptake of transmitter into vesicles is energy-dependent. Vesicular transporters can concentrate neurotransmitters up to 100,000-fold relative to their concentration in the cytoplasm. Uptake of transmitters by the transporters is extremely rapid, enabling vesicles to be quickly refilled after they release their transmitter and are retrieved by endocytosis; this is important for maintaining the supply of releasable vesicles during periods of rapid nerve firing (see Chapter 12).

Although the specificity of transporters is quite marked—the ACh transporter does not transport choline or any other transmitter, and the glutamate transporter hardly carries any aspartate at all—the affinity for their transmitters can be quite low. For example, the Michaelis constant ($K_{\rm m}$) for ACh or glutamate transport is approximately 0.3 mM, and for GABA 5 to 10 mM. This low affinity for transmitter presumably does not limit synaptic transmission, however, because the concentrations of these substances in the cytoplasm are normally very high. In contrast, amine transporters have a substantially higher affinity for monoamines ($K_{\rm m}$ of approximately 1–15 μ M), appropriate for the lower cytoplasmic concentration of these substances.

Transporters and V-ATPases are present in the membranes of both small synaptic vesicles and large dense-core vesicles. Vesicular transporters are the targets of several important pharmacological agents. Reserpine and tetrabenazine both inhibit uptake of amine transmitters by binding to the vesicular monoamine transporter and have played a historic role in development of the biogenic amine hypothesis of depression (see Chapter 63). The psychostimulants amphetamine and 3,4-methylenedioxy-*N*-methylamphetamine (MDMA or ecstasy) deplete vesicles of amine transmitter

A Monoamines

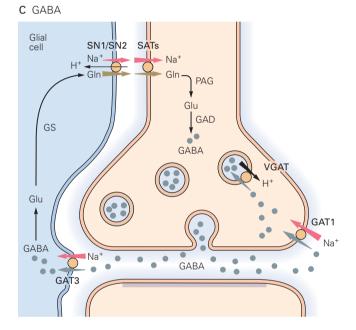

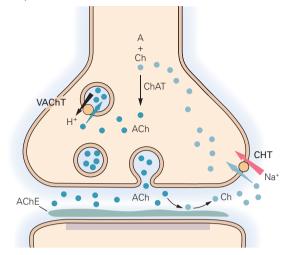

Figure 13–1 Small-molecule transmitters are transported from the cytosol into vesicles or from the synaptic cleft to the cytosol by transporters. Most small-molecule neurotransmitters are released by exocytosis from the nerve terminal and act on specific postsynaptic receptors. The signal is terminated and transmitter recycled by specific transporter proteins located at the nerve terminal or in surrounding glial cells. Transport by these proteins (orange circles) is driven by the H⁺ (black arrows) or Na⁺ (red arrows) electrochemical gradients. (Adapted, with permission, from Chaudhry et al. 2008.)

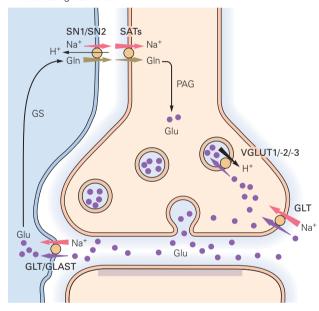

A. Three distinct transporters mediate reuptake of monoamines across the plasma membrane. The dopamine transporter (DAT), norepinephrine transporter (NET), and serotonin transporter (SERT) are responsible for the reuptake (dark blue arrows) of their cognate transmitters. The vesicular monoamine transporter VMAT2 transports all three monoamines into synaptic vesicles for subsequent exocytotic release.

B. Cholinergic signaling is terminated by metabolism of acetylcholine (ACh) to the inactive choline and acetate by acetylcholinesterase (AChE), which is located in the synaptic cleft. Choline (Ch) is transported back into the nerve terminal

B Acetylcholine

D Mediate glutamate

(**light blue arrow**) by the choline transporter (CHT), where choline acetyltransferase (ChAT) subsequently catalyzes acetylation of choline to reform ACh. The ACh is transported into the vesicle by the vesicular ACh transporter (VAChT).

C. At GABAergic and glycinergic nerve terminals the GABA transporter (GAT1) and glycine transporter (GLYT2, not shown) mediate reuptake of GABA and glycine (gray arrow), respectively. GABA may also be taken up by surrounding glial cells (eg, by GAT3). In the glial cells glutamate (Glu) is converted by glial glutamine synthetase to glutamine (Gln). Glutamine is transported back to the nerve terminal by the concerted action of the system N transporter (SN1/SN2) and system A transporter (SAT) (brown arrows). The glial transporter GLYT1 (not shown) also contributes to the clearance of glycine.

D. After release from excitatory neuronal terminals the majority of glutamate is taken up by surrounding glial cells (eg, by GLT and GLAST) for conversion to glutamine, which is subsequently transported back to the nerve terminals by SN1/SN2 and a type of SAT (SATx) (brown arrows). Reuptake of glutamate (purple arrow) at glutamatergic terminals also has been demonstrated for a GLT isoform.

molecules, most likely by dissipating the pH gradient. These compounds may also compete with the amine transmitters for uptake, and are presumed to interact directly with the transporters, though it is not yet clear whether these drugs and the actual transmitters bind to the same or different sites on the transporters.

Drugs that are sufficiently similar to the normal transmitter substance can act as false transmitters. These are packaged in vesicles and released by exocytosis as if they were true transmitters, but they often bind only weakly or not at all to the postsynaptic receptor for the natural transmitter. Therefore, their release decreases the efficacy of transmission. Several drugs that have been used to treat hypertension, such as phenylethylamines, are taken up into adrenergic terminals and replace norepinephrine in synaptic vesicles. When released, these drugs are not as potent as norepinephrine at postsynaptic adrenergic receptors. Some of these drugs must be actively taken up into neurons by transporters in the external membrane of the cell. These transporter molecules are discussed later in this chapter.

Many Neuroactive Peptides Serve as Transmitters

With the exception of dopamine β-hydroxylase, the enzymes that catalyze the synthesis of the low-molecular-weight neurotransmitters are found in the cytoplasm. These enzymes are synthesized on free polysomes in the cell body and are distributed throughout the neuron by axoplasmic flow. Thus small-molecule transmitter substances can be formed in all parts of the neuron; most importantly, they can be synthesized at nerve terminals where they are released.

In contrast, neuroactive peptides are derived from secretory proteins that are formed in the cell body. Like other secretory proteins, neuroactive peptides or their precursors are first processed in the endoplasmic reticulum and then move to the Golgi apparatus to be processed further. They then leave the Golgi apparatus in secretory granules that are destined to become large dense-core vesicles, which are moved to axon terminals by fast axonal transport.

More than 50 short peptides are pharmacologically active in nerve cells (Table 13–2). Some act as hormones on targets outside the brain (eg, angiotensin and gastrin) or are products of neuroendocrine secretion (eg, oxytocin, vasopressin, somatostatin, luteinizing hormone, and thyrotropin-releasing hormone). In addition to being hormones in some tissues, they also act as neurotransmitters when released close

Table 13–2 Neuroactive Mammalian Brain Peptides Categorized According to Tissue Localization

Category	Peptide
Hypothalamic releasing hormones	Thyrotropin-releasing hormone Gonadotropin-releasing hormone Somatostatin Corticotropin-releasing hormone Growth hormone-releasing hormone

to a target neuron, where they can cause inhibition or excitation, or both.

Neuroactive peptides have been implicated in modulating sensory perception and emotions. Some peptides, including substance P and enkephalins, are preferentially located in regions of the central nervous system involved in the perception of pain. Other neuropeptides regulate complex responses to stress; these peptides include γ -melanocyte stimulating hormone, corticotropin-releasing hormone (CRH), adrenocorticotropin (ACTH), and β -endorphin.

Although the diversity of neuroactive peptides is enormous, as a class these chemical messengers share a common cell biology. The most direct way to determine relatedness between peptides is to compare either the amino acid sequences of the peptides or the nucleotide base sequences in the genes that encode them. A striking generality is that neuroactive peptides are grouped in families with members that have similar sequences of amino acid residues. At least 10 have been identified; the seven main families are listed in Table 13–3.

Several different neuroactive peptides can be encoded by a single continuous messenger RNA (mRNA), which is translated into one large polyprotein precursor (Figure 13–2). Polyproteins can serve as a mechanism for amplification by providing more than one copy of the same peptide from the one precursor. As an example, the precursor of glucagon contains two copies of the hormone. Polyproteins generate diversity by producing several distinct peptides cleaved from one precursor, as in the case of the opioid peptides.

The processing of more than one functional peptide from a single polyprotein is not unique to neuroactive peptides. The mechanism was first described for proteins encoded by small RNA viruses. Several viral polypeptides are produced from the same viral polyprotein, and all contribute to the generation of new virus particles. As with the virus, where the different proteins obviously serve a common biological purpose (formation of new viruses), a neuronal polypeptide will in many instances yield peptides that work together to serve a common physiological goal. Sometimes the biological functions appear to be more complex, as peptides with related or antagonistic activities can be generated from the same precursor.

A particularly striking example of this form of synergy is the group of peptides formed from the precursor of egg-laying hormone (ELH), a set of neuropeptides that govern diverse reproductive behaviors in the marine mollusk *Aplysia*. Egg-laying hormone can act as a hormone causing the contraction of duct muscles; it can also act as a neurotransmitter to alter the firing of several neurons involved in producing behaviors, as do the other peptides cut from the polyprotein.

The processing of polyproteins to neuroactive peptides takes place within the neuron's major intracellular membrane system and in vesicles. Several peptides are produced from a single polyprotein by limited and specific proteolytic cleavage catalyzed by proteases present within these internal membrane systems. Some of these enzymes are serine proteases, a class that also includes the pancreatic enzymes trypsin and chymotrypsin. As with trypsin, the site of the peptide bond cleaved is determined by the presence of one or two dibasic amino acid residues (lysine and arginine) in the substrate protein. Cleavage occurs between residue X and two dibasic residues (eg, X-Lys-Lys, -X-Lys-Arg,

Table 13-3 Some Families of Neuroactive Peptides

Family	Peptide members
Opioids	Opiocortin, enkephalins, dynorphin, FMRFamide
Neurohypophyseal hormones	Vasopressin, oxytocin, neurophysins
Tachykinins	Substance P, physalaemin, kassinin, uperolein, eledoisin, bombesin, substance K
Secretins	Secretin, glucagon, vasoactive intestinal peptide, gastric inhibitory peptide, growth hormone releasing factor, peptide histidine isoleucine amide
Insulins	Insulin, insulin-like growth factors I and II
Somatostatins	Somatostatins, pancreatic polypeptide
Gastrins	Gastrin, cholecystokinin

FMRFamide, Phe-Met-Arg-Phe-amide.

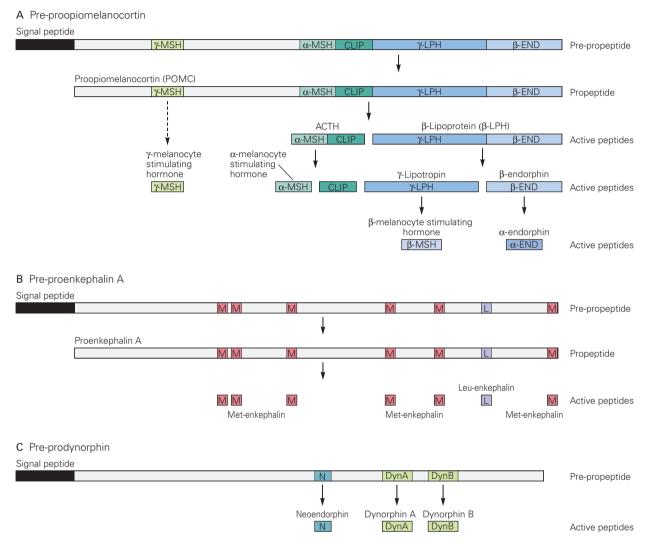

Figure 13-2 Hormone and neuropeptide precursors are processed differentially. In several instances neuropeptides and hormones arise from larger precursor molecules that require multiple rounds of proteinase-mediated cleavage. These precursors are processed differentially to yield their specific peptide products. Transport of these precursors through the membrane of the endoplasmic reticulum is initiated by a hydrophobic signal sequence. Internal cleavages often occur at basic residues within the polypeptide. Moreover, these precursors have key cysteine residues and sugar moieties that play roles in their processing and function. Generally, the first iteration of processing begins with the newly synthesized polyprotein precursor (known as the pre-propeptide form), which contains an amino-terminal signal sequence that is cleaved to generate a smaller molecule, the propeptide. Differential processing of the three families of peptides gives rise to the opioid peptides— POMC (proopiomelanocortin), enkephalin, and dynorphin.

- A. The POMC precursor is processed differently in different lobes of the pituitary gland, resulting in α -melanocyte stimulating hormone (α -MSH) and γ -MSH, corticotropin-like intermediate lobe peptide (CLIP), and β -lipotropin (β -LPH). β -LPH is cleaved to yield γ -LPH and β -endorphin (β -END), which themselves yield β -melanocyte stimulating hormone (β -MSH) and α -endorphin (α -END), respectively. The endoproteolytic cleavages within ACTH (adrenocorticotropic hormone) and β -LPH take place in the intermediate lobe but not the anterior lobe.
- **B.** Similar principles are evident in the processing of the enkephalin precursor, which gives rise to six Met-enkephalin peptides and one Leu-enkephalin peptide.
- C. The dynorphin precursor is also cleaved into at least three peptides, including α -neoendorphin (N), dynorphin A (Dyn A), and dynorphin B (Dyn B), which are related to Leu-enkephalin since the amino-terminal sequences of all three peptides contain the sequence of Leu-enkephalin.

-X-Arg-Lys, or -X-Arg-Arg). Although cleavage is common at dibasic residues, it can also occur at single basic residues, and polyproteins sometimes are cleaved at other peptide bonds.

Other types of peptidases also catalyze the limited proteolysis required for processing polyproteins into neuroactive peptides. Among these are thiol endopeptidases (with catalytic mechanisms like that of pepsin), amino peptidases (which remove the N-terminal amino acid of the peptide), and carboxypeptidase B (an enzyme that removes an amino acid from the N-terminal end of the peptide if it is basic).

Neurons that produce the same polyprotein may release different neuropeptides as a consequence of differences in the way the polyprotein is processed. An example is proopiomelanocortin (POMC), one of the three branches of the opioid family. POMC is found in neurons of the anterior and intermediate lobes of the pituitary, in the hypothalamus and several other regions of the brain, as well as in the placenta and the gut. The same mRNA for POMC is found in all of these tissues, but different peptides are produced from POMC in different tissues in a regulated manner. One possibility is that two neurons that process the same polyprotein differently might contain proteases with different specificities within the lumina of the endoplasmic reticulum, Golgi apparatus, or vesicles. Alternatively, the two neurons might contain the same processing proteases, but each cell might glycosylate the common polyprotein at different sites, thereby protecting different regions of the polypeptide from cleavage.

Peptides and Small-Molecule Transmitters Differ in Several Ways

The metabolism of peptides differs from that of small-molecule transmitters in several important ways: their site of synthesis, the type of vesicle in which they are stored, and the mechanism of exocytotic release. Whereas small-molecule transmitters are chiefly synthesized at axon terminals, neuroactive peptides are made only in the cell body because their synthesis as secretory proteins requires the transfer of the nascent polypeptide chain into the lumen of the endoplasmic reticulum (see Chapter 4).

The large dense-core vesicles in which peptides are stored originate from the trans-Golgi network through a pathway different from that of the synaptic vesicles transporting small-molecule transmitters. Large dense-core vesicles are homologous to the secretory granules of non-neuronal cells and follow the *regulated*

secretory pathway. Biogenesis of synaptic vesicles also begins in the trans-Golgi network in the form of precursor vesicles produced in the cell body. These vesicles are then transported down the axon to presynaptic terminals, where the precursor vesicle is thought to first fuse with the presynaptic membrane through the *constitutive* secretory pathway. The precursor vesicle membrane is then retrieved through endocytosis and processed through local endosomes to yield a mature synaptic vesicle capable of participating in the release of neurotransmitter through regulated exocytosis.

Although both types of vesicles contain many similar proteins, dense-core vesicles lack several proteins needed for release at the active zones. The membranes from dense-core vesicles are used only once; new dense-core vesicles must be synthesized in the cell body and transported to the axonal terminals by anterograde transport. Moreover no uptake mechanisms exist for neuropeptides. Thus once a peptide is released, a new supply must arrive from the cell body before release can take place again. There is increasing evidence for local protein synthesis in axons, and this might also be a source of new peptide for release.

The large dense-core vesicles release their contents by an exocytotic mechanism that is not specialized to nerve cells and that does not require active zones; release can thus take place anywhere along the membrane of the axon terminal. As in other examples of regulated secretion, exocytosis of the dense-core secretory vesicles depends on a general elevation of intracellular Ca²⁺ through voltage-gated Ca²⁺ channels that are not localized to the site of release. As a result, this form of exocytosis is slow and requires high stimulation frequencies to raise Ca²⁺ to levels sufficient to trigger release. This is in contrast to the rapid exocytosis of synaptic vesicles following a single action potential, which results from the large, rapid increase in Ca²⁺ through voltage-gated Ca2+ channels tightly clustered at the active zone.

Peptides and Small-Molecule Transmitters Coexist and Can Be Co-released

Neuroactive peptides, small-molecule transmitters, and other neuroactive molecules can coexist in the same dense-core vesicles of a neuron (see Chapter 4). In mature neurons the combination usually consists of one of the small-molecule transmitters and one or more peptides derived from a polyprotein. For example, ACh and vasoactive intestinal peptide (VIP) can be released together and work synergistically on the same target cells.

Another example is calcitonin gene–related peptide (CGRP), which in most spinal motor neurons is packaged together with ACh, the transmitter used at the neuromuscular synapse. CGRP activates adenylyl cyclase, raising cyclic adenosine monophosphate (cAMP) levels and cAMP-dependent protein phosphorylation in the target muscles (see Chapter 11). Increased protein phosphorylation results in an increase in the force of contraction. One other example is the co-release of glutamate and dynorphin in neurons of the hippocampus, where glutamate is excitatory and dynorphin inhibitory. Because postsynaptic target cells have receptors for both chemical messengers, all of these examples of co-release are also examples of cotransmission.

As already described, the dense-core vesicles that release peptides differ from the small clear vesicles that release only small-molecule transmitters. The peptide-containing vesicles may or may not contain small-molecule transmitter, but both types of vesicles contain ATP. As a result ATP is released by exocytosis of both large dense-core vesicles and synaptic vesicles. Moreover, it appears that ATP may be stored and released in a number of distinct ways: (1) ATP is co-stored and co-released with transmitters, (2) ATP release is simultaneous but independent of transmitter release, and (3) ATP is released alone. Co-release of ATP (which after release can be degraded to adenosine) may be an important illustration that coexistence and co-release do not necessarily signify cotransmission. ATP, like many other substances, can be released from neurons but still not be effective if there are no receptors nearby.

As mentioned above, one criterion for judging whether a particular substance is used as a transmitter is that the substance is present in high concentrations in a neuron. Identification of transmitters in specific neurons has been important in understanding synaptic transmission and a variety of histochemical methods are used to detect chemical messengers in neurons (Box 13–2).

An interesting example of co-release of two small-molecule transmitters is that of glutamate and dopamine by neurons projecting to the ventral striatum. This co-release may have important implications for modulation of motivated behaviors. It has been established that the vesicular transporter VGlut2 gathers glutamate into vesicles in these dopaminergic terminals, and glutamate is released together with dopamine in response to different patterns of dopaminergic neuron firing. In addition, glutamate uptake also enhances vesicular monoamine storage by increasing the pH gradient that drives vesicular monoamine transport, providing a novel presynaptic mechanism to regulate quantal size.

Removal of Transmitter from the Synaptic Cleft Terminates Synaptic Transmission

Timely removal of transmitters from the synaptic cleft is critical to synaptic transmission. If transmitter molecules released in one synaptic action were allowed to remain in the cleft after release, they would prevent new signals from getting through. The synapse would become refractory, mainly because of receptor desensitization resulting from continued exposure to transmitter. Transmitters are removed from the cleft by three mechanisms: diffusion, enzymatic degradation, and reuptake. Diffusion removes some fraction of all chemical messengers.

Enzymatic degradation of transmitter is used only by cholinergic synapses. At the neuromuscular junction the active zone of the presynaptic nerve terminal is situated just above the junctional folds of the muscle membrane. The ACh receptors are located at the surface of the muscle facing the release sites and do not extend deep into the folds (see Figure 9–1), whereas acetylcholinesterase is anchored to the basement membrane within the folds. This anatomical arrangement of transmitter, receptor, and degradative enzyme serves two functions.

First, on release ACh reacts with its receptor; after dissociation from the receptor the ACh diffuses into the cleft and is hydrolyzed to choline and acetate by acetylcholinesterase. As a result, the transmitter molecules are used only once. Thus one function of the esterase is to punctuate the synaptic message. The second function is to recapture the choline that otherwise might be lost by diffusion away from the synaptic cleft. Once hydrolyzed by the esterase, the choline lingers in the reservoir provided by the junctional folds and is later taken back up into cholinergic nerve endings by a high-affinity choline transporter. (There is no uptake mechanism for ACh itself.) In addition to acetylcholinesterase, ACh is also degraded by another esterase, butyrylcholinesterase, which can degrade other molecules including cocaine and the paralytic drug succinylcholine. However, the precise functions of butyrylcholinesterase remain to be more fully understood.

Many other enzymatic pathways that degrade released transmitters are not involved in terminating synaptic transmission but are important for controlling the concentration of the transmitter within the neuron or for inactivating transmitter molecules that have diffused away from the synaptic cleft. Many of these degradation enzymes are important clinically—they provide sites for drug action and serve as diagnostic indicators. For example, monoamine oxidase (MAO) inhibitors,

Box 13–2 Detection of Chemical Messengers and Their Processing Enzymes within Neurons

Powerful histochemical techniques are available for detecting both small-molecule transmitter substances and neuroactive peptides in histological sections of nervous tissue.

Catecholamines and serotonin, when reacted with formaldehyde vapor, form fluorescent derivatives. In an early example of transmitter histochemistry, the Swedish neuroanatomists Bengt Falck and Nils Hillarp found that the reaction can be used to locate transmitters with fluorescence microscopy under properly controlled conditions.

Because individual vesicles are too small to be resolved by the light microscope, the exact position of the vesicles containing the transmitter can be inferred by comparing the distribution of fluorescence under the light microscope with the position of vesicles under the electron microscope.

Histochemical analysis can be extended to the ultrastructure of neurons under special conditions. Fixation of nervous tissue in the presence of potassium permanganate, chromate, or silver salts intensifies the electron density of vesicles containing biogenic amines and thus brings out the large number of dense-core vesicles that are characteristic of aminergic neurons.

It is also possible to identify neurons that express the gene for a particular transmitter enzyme or peptide precursor. Many methods for detecting specific mRNAs depend on the nucleic acid hybridization. One such method is in situ hybridization.

Two single strands of a nucleic acid polymer will pair if their sequence of bases is complementary. With in situ hybridization the strand of noncoding DNA (the negative or antisense strand or its corresponding RNA) is applied to tissue sections under conditions suitable for hybridizing with endogenous (sense) mRNA. If the probes are radiolabeled, autoradiography reveals the locations of neurons that contain the complex formed by the labeled complementary nucleic acid strand and the mRNA.

Hybrid oligonucleotides synthesized with nucleotides containing base analogs tagged chemically, fluorescently, or immunoreactively can be localized cytochemically. Both labels can be used at the same time (Figure 13–3A). More recent modifications of these approaches involve viral or transgenic expression of proteins fused to variants of green fluorescent protein (Figure 13–3B).

Transmitter substances can also be localized by immunocytochemistry. Amino acid transmitters, biogenic

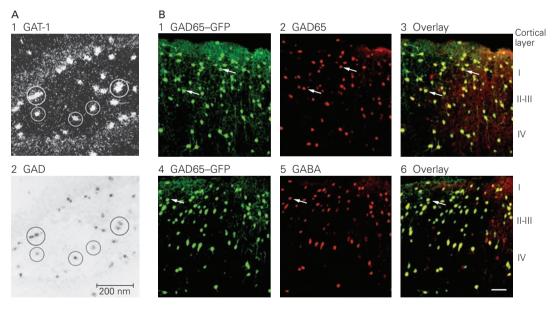

Figure 13–3 Histochemical techniques for visualizing chemical messengers.

A. A light-microscope section of the hippocampus of a rat. **1.** In situ hybridization using a probe for the mRNA encoding GAT-1, a GABA transporter. The probe was end-labeled with α - 35 S-dATP and visualized by clusters of silver grains in the overlying autoradiographic photographic emulsion. Neurons expressing both transcripts were labeled by the phosphatase reaction product and by silver grains. **Circles** enclose nerve cell bodies that contain both labels. **2.** In situ hybridization of the mRNA for glutamic acid decarboxylase (GAD), the specific biosynthetic enzyme for GABA, was carried out with an oligonucleotide probe linked to

the enzyme alkaline phosphatase. The GAD probe was visualized by accumulation of colored alkaline phosphatase reaction product in the cytoplasm. **Circles** enclose areas containing cells with the greatest reactivity. (Reproduced, with permission, from Sara Augood.)

B. Images of neocortex from a GAD65GFP transgenic mouse in which green fluorescent protein (GFP) is expressed under the control of the GAD65 promotor. GFP is co-localized with GAD65 (1-3) and GABA (4-6) (both detected by indirect immunofluorescence) in neurons in the supragranular layers. Most of the GFP-positive neurons are immunopositive for GAD65 and GABA (arrows). Scale bar = 100 μ m. (Adapted, with permission, from López-Bendito et al. 2004.)

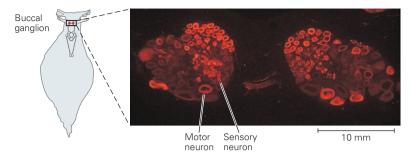

Figure 13–4 An immunochemical technique visualizes a neuropeptide. The buccal ganglion of the marine snail *Aplysia* contains the sensory, motor, and interneurons that control the rhythmic movements of the feeding apparatus of the animal. A cryostat section of the bilaterally symmetrical buccal ganglion is labeled with an antibody raised against FMRFamide. The staining shows immunoreactive

FMRFamide in certain sensory neurons (most of the cells with the small cell bodies) as well as certain motor neurons (cells with larger cell bodies). Some of these cells contain one or more other peptides or conventional transmitters such as ACh. (Reproduced, with permission, from Lloyd et al. 1987.)

amines, and neuropeptides have a primary amino group that becomes covalently fixed within the neurons; this group becomes cross-linked to proteins by aldehydes, the usual fixatives used in microscopy.

For immunohistochemical localization, specific antibodies against the transmitter substances are necessary. Antibodies specific to serotonin, histamine, and many neuroactive peptides can be detected by a second antibody (in a technique called *indirect immunofluorescence*). As an example, if the first antibody is rabbitderived, the second antibody can be goat antibody raised against rabbit immunoglobulin.

These commercially available secondary antibodies are tagged with fluorescent dyes and used under the fluorescence microscope to locate antigens in regions of individual neurons—cell bodies, axons, and sometimes terminals (Figures 13–3, 13–4).

Ultrastructure localization can be achieved by immunochemical techniques, usually involving a peroxidase-antiperoxidase system. Another method is to use antibodies linked to gold particles, which are electron-dense (Figure 13–5). Spheres of colloidal gold can be generated with precise diameters in the nanometer range, and because they are electron-dense they can be seen in the electron microscope. This technique has the additional useful feature that more than one specific antibody can be examined in the same tissue section if each antibody is linked to gold particles of different sizes.

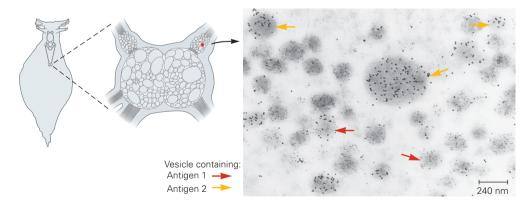

Figure 13–5 Electron-opaque gold particles linked to antibody are used to locate antigens in tissue at the ultrastructural level. The electron micrograph shows a section through the cell body of an *Aplysia* bag cell. Bag cells control reproductive behavior by releasing a group of neuropeptides cleaved from the egg-laying hormone (ELH) precursor. The cells contain several kinds of densecore vesicles. The cell shown here was treated with two antibodies against different regions of the ELH precursor.

One antibody was raised in rabbits and the other in rats. These antibodies were detected with anti-rabbit or anti-rat immunoglobulins (secondary antibodies) raised in goats. Each secondary antibody was coupled to colloidal gold particles of a distinct size. Vesicles identified by antigen 1 are smaller than vesicles identified by antigen 2, indicating that the specific fragments cleaved from the precursor are localized in different vesicles. (Reproduced, with permission, from Fisher et al. 1988.)

which block the degradation of amine transmitters, are used to treat depression and Parkinson disease. Determination of the concentrations of the metabolites of catechol-O-methyltransferase (COMT), which is important for degrading biogenic amines and found in the cytoplasm of most cells, provides an index of the efficacy of drugs that affect the synthesis or degradation of the biogenic amines in nervous tissue. COMT is thought to play a particularly important role in regulating cortical dopamine levels due to the low levels of the dopamine uptake transporter.

The mechanisms for removing neuropeptides from the synaptic cleft are slow diffusion and proteolysis by extracellular peptidases. In contrast, smallmolecule transmitters are removed more quickly from the synaptic cleft.

The critical mechanism for inactivation of most neurotransmitters is reuptake at the plasma membrane. This mechanism serves the dual purposes of terminating the synaptic action of the transmitter as well as recapturing transmitter molecules for subsequent reuse. High-affinity uptake, with binding constants of 25 μM or less for the released transmitter, is mediated by transporter molecules in the membranes of nerve terminals and glial cells. Unlike vesicular transporters, which are powered by the H^+ electrochemical gradient in a countertransport mechanism, plasma membrane transporters are driven by the Na $^+$ electrochemical gradient through a symport mechanism in which Na $^+$ ions and transmitter move in the same direction.

Each type of neuron has its own characteristic uptake mechanism. For example, noncholinergic neurons do not take up choline with high affinity. Certain powerful psychotropic drugs can block uptake processes. For example, cocaine blocks the uptake of dopamine, norepinephrine, and serotonin; the tricyclic antidepressants and selective serotonin reuptake inhibitors, such as fluoxetine (Prozac), block uptake of serotonin or norepineprhine. The application of appropriate drugs that block transporter molecules can prolong and enhance synaptic signaling by the biogenic amines and GABA. In some instances drugs act both on transporter molecules on the neuron's surface and on vesicular transporters within the cell. For example, amphetamines must be actively taken up by the dopamine transporter on the external membrane of the neuron before they can operate on the vesicular transporter for amine transmitters.

Transporter molecules for neurotransmitters belong to two distinct groups that are different in both structure and mechanism. High-resolution structures of bacterial homologs from each of these families have been solved recently, which has greatly advanced our understanding of transporter mechanisms. One group, the neurotransmitter sodium symporters (NSS), is a superfamily of transmembrane proteins that thread through the plasmalemma 12 times and includes the transporters of GABA, glycine, norepinephrine, dopamine, serotonin, osmolytes, and amino acids. The other consists of transporters of glutamate; these proteins traverse the plasmalemma eight times and contain two helical hairpins that seem to serve a role in gating access of substrate from each side of the membrane. Each group includes several transporters for each transmitter substance; for example, there are multiple GABA, glycine, and glutamate transporters, each with somewhat different localization, function, and pharmacology.

The two groups can be distinguished functionally. Although both are driven by the electrochemical potential provided by the Na⁺ gradient, transport of glutamate requires the countertransport of K+, whereas transport by the NSS usually requires the cotransport of a Cl⁻ ion. During transport of glutamate one negatively charged molecule of the transmitter is imported with three Na+ ions and one proton (symport) in exchange for the export of one K⁺. This leads to a net influx of two positive charges for each transport cycle, generating an inward current. As a result of this charge transfer, the negative resting potential of the cell generates a large inward driving force that results in an enormous gradient of glutamate across the cell membrane. In contrast, the NSS proteins transport one to three Na⁺ ions and one Cl⁻ ion together with their substrates. Under most conditions the electrochemical driving force is sufficient for transporters to transport transmitter into the cell, thereby concentrating it inside the cell.

An Overall View

Information carried by a neuron is encoded in electrical signals that travel along its axon to a synapse, where these signals are transformed and carried across the synaptic cleft by one or more chemical messengers.

The two major classes of chemical messengers, small-molecule transmitters and neuroactive peptides, are packaged in vesicles within the presynaptic neuron. After their synthesis in the cytoplasm, small-molecule transmitters are taken up and concentrated in vesicles, where they are protected from degradative enzymes that maintain a constant level of transmitter substance in the cytoplasm. Synaptic vesicles are highly concentrated in nerve endings. Because they are quickly replenished during synaptic activity, much of the

small-molecule transmitter in the neuron must be synthesized locally at the terminals.

In contrast, the protein precursors of neuroactive peptides are synthesized only in the cell body; the neuropeptides become packaged in secretory granules and vesicles that are carried from the cell body to the terminals by axoplasmic transport. Unlike the vesicles that contain small-molecule transmitters, these vesicles are not refilled at the terminal.

Given their central importance in brain function, it is not surprising that the enzymes that regulate transmitter biosynthesis are under tight regulatory control. Changes in neuronal activity can produce homeostatic changes in the levels of these enzymes. This regulation can occur both post-translationally in the cytoplasm, as a result of phosphorylation and dephosphorylation reactions, and by transcriptional contol in the nucleus.

Precise mechanisms for terminating transmitter actions represent a key step in synaptic transmission that is nearly as important as transmitter synthesis and release. Some released transmitter is lost as a result of simple diffusion out of the synaptic cleft. However, for the most part, transmitter actions are terminated by specific molecular reactions. For example, acetylcholine is rapidly hydrolyzed by acetylcholinesterase to choline and acetate, whereas glutamate is taken up into presynaptic terminals and glia by specific transporters that are driven by ion gradients. Some of the most potent psychoactive compounds act by interfering with transmitter reuptake. The psychostimulatory effects of cocaine result from its action to prevent reuptake of catecholamines whereas the blockade of serotonin transporters are responsible for the antidepressant effects of the selective serotonin reuptake inhibitors (SSRIs).

Can we arrive at a comprehensive and precise definition of a neurotransmitter? Probably not, as the definition is empirical. The first step in understanding the molecular strategy of chemical transmission usually involves identifying the contents of synaptic vesicles. Except for those instances in which transmitter is released by transporter molecules or by diffusion through the membrane (in the case of gases and lipid metabolites, see Chapter 11), only molecules suitably packaged in vesicles can be released from a neuron's terminals. But not all molecules released by a neuron are chemical messengers—only those that bind to appropriate receptors and initiate functional changes in that target neuron can usefully be considered neurotransmitters.

Information is transmitted when transmitter molecules bind to receptor proteins in the membrane of another cell, causing them to change shape. Once the molecules of transmitter are bound, the receptor

generates electrical or metabolic signals in the postsynaptic cell. The co-release of several neuroactive substances onto appropriate postsynaptic receptors permits great diversity of information to be transferred in a single synaptic action.

Postscript: Diagnosis of Motor Unit Disorders Is Aided by Laboratory Criteria

... to move things is all that mankind can do, for such the sole executant is muscle, whether in whispering a syllable or in felling a forest.

Charles Sherrington, 1924

THE MAJOR CONSEQUENCE OF THE elaborate information processing that takes place in the brain is the contraction of skeletal muscles. Indeed, animals are distinguishable from plants by their ability to make precise, goal-directed movements of their body parts. As we shall see in Chapter 16, the problem of deciding when and how to move is, to a large degree, the driving force behind the evolution of the nervous system.

In all but the most primitive animals, specialized muscle cells generate movement. There are three general types of muscles: Smooth muscle is used primarily for internal actions such as peristalsis and control of blood flow; cardiac muscle is used exclusively for pumping blood; and skeletal muscle is used primarily for moving bones. In this chapter we examine a variety of neurological disorders in mammals that affect movement by altering action potential conduction in a motor nerve, synaptic transmission from nerve to muscle, or muscle contraction itself.

In 1925 Charles Sherrington introduced the term *motor unit* to designate the basic unit of motor function—a motor neuron and the group of muscle fibers it innervates (see Chapter 34). The number of muscle fibers innervated by a single motor neuron varies widely throughout the body, depending on the dexterity of the movements controlled and the mass of the

body part to be moved. Thus motor units with fewer than 100 muscle fibers finely control eye movements, whereas in the leg a single motor unit contains up to 1,000 muscle fibers. In each case all the muscles innervated by a motor unit are of the same type. Moreover, motor units are recruited in a fixed order for both voluntary and reflex movements. The smallest motor units are the first to be recruited, joined later by larger units as muscle force increases.

The motor unit is a common target of disease. The distinguishing features of diseases of the motor unit vary depending on which functional component is primarily affected: (1) the cell body of the motor or sensory neuron, (2) the corresponding axons, (3) the neuromuscular junction (the synapse between the motor axon and muscle), or (4) the muscle fibers that are innervated by the motor neuron. Accordingly, disorders of the motor unit have traditionally been classified as motor neuron diseases, peripheral neuropathies, disorders of the neuromuscular junction, or primary muscle diseases (myopathies) (Figure 14–1).

Peripheral neuropathies arise from abnormal function of motor neurons or their axons, leading to weakness of movement. Most peripheral neuropathies also involve sensory neurons, leading to problems in sensation. In some rare motor neuron diseases the motor neurons and motor tracts in the spinal cord degenerate but sensory nerves are spared. In *myopathies* weakness is caused by degeneration of the muscles with little or

no change in motor neurons. In neuromuscular junction diseases alterations in the synapse lead to weakness that may be intermittent. Clinical and laboratory studies usually allow one to distinguish disorders of peripheral nerves from those of the neuromuscular junction or muscle (see Postscript to this chapter).

Disorders of the Peripheral Nerve, Neuromuscular Junction, and Muscle Can Be Distinguished Clinically

When a peripheral nerve is cut, the muscles innervated by that nerve immediately become paralyzed and then waste progressively. Because the nerve carries sensory as well as motor fibers, sensation in the area innervated by the nerve is also lost and tendon reflexes are lost immediately. The term *atrophy* (literally, lack of nourishment) refers to the wasting away of a once-normal muscle. Because of historical usage *atrophy* appears in the names of several diseases that are now regarded as neurogenic.

The main symptoms of the myopathies often include difficulty in walking or lifting. Other, less common symptoms include inability of the muscle to relax (myotonia), cramps, pain (myalgia), or the appearance in the urine of the heme-containing protein that gives muscle its red color (myoglobinuria). The muscular dystrophies are myopathies with special characteristics: The diseases are inherited, all symptoms are caused by

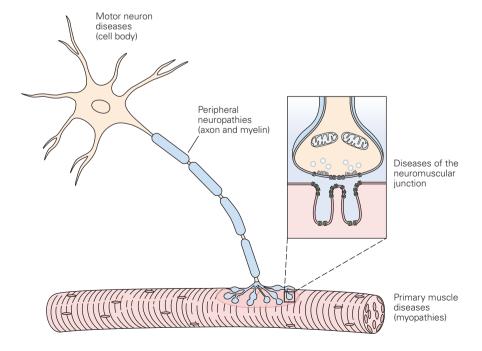

Figure 14–1 Classification of the four types of motor unit disorders is based on the part of the motor unit that is affected.

weakness, the weakness becomes progressively more severe, and signs of degeneration and regeneration are seen histologically.

Distinguishing neurogenic and myopathic diseases may be difficult because both produce weakness of muscle. Classification and differential diagnosis of these diseases involve both clinical and laboratory criteria. As a first approximation, weakness of the distal limbs most often indicates a neurogenic disorder, whereas proximal limb weakness signals a myopathy. Fasciculations-twitches of muscle that are visible through the skin-are often signs of neurogenic diseases. They result from involuntary but synchronous contractions of all muscle fibers in a motor unit. Fibrillations—spontaneous contractions of single muscle fibers—can also be signs of on going denervation of muscle. Fibrillations are not visible but can be recorded with an electromyogram (EMG). The electrical record of a fibrillation is a low-amplitude potential that reflects electrical activity in a single muscle cell. Electrophysiological studies suggest that fasciculations arise in the motor nerve terminal.

In diagnosing motor neuron disorders, clinical neurologists distinguish between lower and upper motor neurons. Lower motor neurons are motor neurons of the spinal cord and brain stem that directly innervate skeletal muscles. Upper motor neurons are neurons in the premotor cortex that issue commands for movements to the lower motor neurons through their axons in the corticospinal (pyramidal) tract. The distinction between upper and lower motor neurons is important clinically because diseases involving each class of neurons produce distinctive symptoms. Disorders of lower motor neurons cause atrophy, fasciculations, decreased muscle tone, and loss of tendon reflexes; disorders of upper motor neurons and their axons result in spasticity, overactive tendon reflexes, and an abnormal plantar extensor reflex (the Babinski sign).

The primary symptom of disorders of the neuromuscular junction is weakness; in some neuromuscular junction diseases this weakness is quite variable even during the course of a single day.

A Variety of Diseases Target Motor Neurons and Peripheral Nerves

Motor Neuron Diseases Do Not Affect Sensory Neurons

The best-known disorder of motor neurons is amyotrophic lateral sclerosis (Lou Gehrig disease). *Amyotrophy* is another word for neurogenic atrophy of muscle;

lateral sclerosis refers to the hardness felt when the pathologist examines the spinal cord at autopsy. This hardness results from the proliferation of astrocytes and scarring of the lateral columns of the spinal cord caused by degeneration of the corticospinal tracts. Some motor neurons are spared, notably those supplying ocular muscles and those involved in voluntary control of bladder sphincters.

The symptoms of amyotrophic lateral sclerosis (ALS) usually start with painless weakness of the arms or legs. Typically the patient, often a man in his 40s or 50s, discovers that he has trouble in executing fine movements of the hands; typing, playing the piano, playing baseball, fingering coins, or working with tools all become awkward.

Most cases of ALS involve both upper and lower motor neurons. Thus the typical weakness of the hand is associated with wasting of the small muscles of the hands and feet and fasciculations of the muscles of the forearm and upper arm. These signs of lower motor neuron disease are often associated with hyperreflexia, an increase in tendon reflexes characteristic of corticospinal upper motor neuron disease.

The cause of most (95%) cases of ALS is unknown; the disease is progressive and ultimately affects muscles of respiration. There is no effective treatment for this fatal condition.

Approximately 10% of cases are inherited as dominant traits. Of these, approximately 25% arise from mutations in the gene encoding the protein copper/zinc cytosolic superoxide dismutase, or SOD1. The fact that this form of the disease is dominantly inherited suggests that the disorder arises from some acquired toxic property of the mutant SOD1 protein. This is underscored by the observation that nearly all mutations causing this form of ALS are missense changes that substitute one or more amino acids in the wild-type, normal protein. The exact neurotoxic property of the mutant enzyme remains unclear.

Strikingly, mice and rats that have high levels of the mutant SOD1 develop an adult-onset form of motor neuron disease that leads to death. By contrast, mice expressing equivalently high levels of normal SOD1 do not develop paralysis. These findings are consistent with the concept that the mutant molecule has acquired one or more forms of cytotoxicity. As with other aspects of normal and abnormal functions of the brain and spinal cord, mouse models of motor neuron disease have proven highly instructive for the study of potential treatments as well as the molecular pathogenesis of the disease.

There are other variants of motor neuron disease. The first symptoms may be restricted to muscles

innervated by cranial nerves, with resulting dysarthria (difficulty speaking) and dysphagia (difficulty swallowing). When cranial symptoms occur alone, the syndrome is called progressive bulbar palsy. (The term *bulb* is used interchangeably with *pons*, the structure at the base of the brain where motor neurons that innervate the face and swallowing muscles reside, and *palsy* means weakness.) If only lower motor neurons are involved, the syndrome is called progressive spinal muscular atrophy.

Progressive spinal muscular atrophy is a developmental disorder of motor neurons and is characterized by weakness, wasting, loss of reflexes, and fasciculations. Most cases arise in infants and are caused by recessively inherited mutations in the gene encoding a protein called survival motor neuron or SMN. Some rare cases begin in late childhood or even early adulthood. The SMN protein is implicated in the trafficking of RNA in and out of the nucleus and in the formation of complexes that are important in RNA splicing. In humans the SMN locus on chromosome 5 has two almost identical copies of the SMN gene. One produces a full length SMN protein, whereas the second expresses a small amount of full-length SMN and a shortened SMN. The loss of full-length SMN from mutations at the main locus can be mitigated to some degree by the shortened SMN protein expressed at the second locus.

Amyotrophic lateral sclerosis and its variants are restricted to motor neurons; they do not affect sensory neurons or autonomic neurons. The acute viral disease poliomyelitis is also confined to motor neurons. These diseases illustrate dramatically the individuality of nerve cells and the principle of selective vulnerability. The basis of this selectivity is, in general, not understood.

Diseases of Peripheral Nerves Affect Conduction of the Action Potential

Diseases of peripheral nerves may affect either axons or myelin. Because motor and sensory axons are bundled together in the same peripheral nerves, disorders of peripheral nerves usually affect both motor and sensory functions. Some patients with peripheral neuropathy report abnormal, frequently unpleasant, sensory experiences similar to the sensations felt after local anesthesia for dental work. These sensations are variously called numbness, pins-and-needles, or tingling. When the sensations occur spontaneously without an external sensory stimulus they are called paresthesias.

Patients with paresthesias usually have impaired perception of cutaneous sensations (pain and temperature), often because the small myelinated fibers that carry these sensations are selectively affected. Proprioceptive sensations (position and vibration) may be lost without loss of cutaneous sensation. Lack of pain perception may lead to injuries. The sensory disorders are more prominent distally (called a glove-and-stocking pattern), possibly because the distal portions of the nerves are most remote from the cell body and therefore most susceptible to disorders that interfere with axonal transport of essential metabolites and proteins.

Peripheral neuropathy is first manifested by weakness that is usually distal. Tendon reflexes are usually depressed or lost, fasciculation is seen only rarely, and wasting does not ensue unless the weakness has been present for many weeks.

Neuropathies may be either acute or chronic. The best-known acute neuropathy is Guillain-Barré syndrome. Most cases follow respiratory infection or infectious diarrhea, but the syndrome may occur without preceding illness. The condition may be mild or so severe that mechanical ventilation is required. Cranial nerves may be affected, leading to paralysis of ocular, facial, and oropharyngeal muscles. The disorder is attributed to an autoimmune attack on peripheral nerves by circulating antibodies. It is treated by removing the offending antibodies by infusions of gamma globulin and plasmapheresis. The blood is removed from a patient, cells are separated from plasma which has the antibodies, and the cells alone are returned to the patient.

The chronic neuropathies vary from the mildest manifestations to incapacitating or even fatal conditions. There are many varieties, including genetic diseases (acute intermittent porphyria, Charcot-Marie-Tooth disease), metabolic disorders (diabetes, vitamin B₁₂ deficiency), intoxication (lead), nutritional disorders (alcoholism, thiamine deficiency), carcinomas (especially carcinoma of the lung), and immunological disorders (plasma cell diseases, amyloidosis). Some chronic disorders, such as neuropathy caused by vitamin B₁₂ deficiency in pernicious anemia, are amenable to therapy.

In addition to being acute or chronic, neuropathies may be categorized as demyelinating (in which the myelin sheath breaks down) or axonal (in which the axon is affected). In demyelinating neuropathies, as might be expected from the role of the myelin sheath in saltatory conduction, conduction velocity is slowed because the axons have lost myelin (discussed below). In axonal neuropathies the myelin sheath is not affected and conduction velocity is normal.

Axonal and demyelinating neuropathies may lead to positive or negative symptoms and signs. The negative signs consist of weakness or paralysis, loss of

tendon reflexes, and impaired sensation resulting from loss of motor and sensory nerves. The positive symptoms of peripheral neuropathies consist of paresthesias that arise from abnormal impulse activity in sensory fibers, and either spontaneous activity of injured nerve fibers or electrical interaction (cross-talk) between abnormal axons, a process called *ephaptic transmission* to distinguish it from normal synaptic transmission. For unknown reasons damaged nerves also become hyperexcitable. Lightly tapping the site of injury can evoke a burst of unpleasant sensations in the region over which the nerve is distributed.

Negative symptoms, which have been studied more thoroughly than positive symptoms, can be attributed to three basic mechanisms: conduction block, slowed conduction, and impaired ability to conduct impulses at higher frequencies. Conduction block was first recognized in 1876 when the German neurologist Wilhelm Erb observed that stimulation of an injured peripheral nerve below the site of injury evoked a muscle response, whereas stimulation above the site of injury produced no response. He concluded that the lesion blocked conduction of impulses of central origin, even when the segment of the nerve distal to the lesion was still functional. Later studies confirmed this conclusion by showing that selective application of diphtheria and other toxins produces conduction block by causing demyelination only at the site of application.

Why does demyelination produce nerve block and how does it lead to slowing of conduction velocity? As discussed in Chapter 6, conduction velocity is much more rapid in myelinated fibers than in unmyelinated axons for two reasons. First, there is a direct relationship between conduction velocity and axon diameter, and myelinated axons tend to be larger in diameter. Second, membrane capacitance in the myelinated regions of the axon is less than at the unmyelinated nodes of Ranvier, greatly speeding up the rate of depolarization and thus conduction. In contrast, when an action potential propagates along long stretches of demyelinated axon it becomes severely attenuated.

When myelination is disrupted by disease, the action potentials in different axons of a nerve begin to conduct at slightly different velocities. As a result, the nerve loses its normal synchrony of conduction in response to a single stimulus (measurement of conduction velocities in peripheral nerves is described in Figure 14–2). This slowing and loss of synchrony are thought to account for some early clinical signs of demyelinating neuropathy. For example, functions that normally depend on the arrival of synchronous bursts of neural activity, such as tendon reflexes and vibratory sensation, are lost soon after the onset of a chronic

neuropathy. As demyelination becomes more severe, conduction becomes blocked. Conduction failure may be intermittent, occurring only at high frequencies of neural firing, or complete.

The Molecular Bases of Some Inherited Peripheral Neuropathies Have Been Defined

Myelin proteins have been found to be affected in some demyelinating hereditary peripheral neuropathies, termed Charcot-Marie-Tooth disease. As in other peripheral neuropathies, muscle weakness and wasting, loss of reflexes, and loss of sensation in the distal parts of the limbs characterize the condition. These symptoms appear in childhood or adolescence and are slowly progressive.

One form (type 1) has the features of a demyelinating neuropathy. Conduction in peripheral nerves is slow, with histological evidence of demyelination followed by remyelination. Sometimes the remyelination leads to gross hypertrophy of the nerves. Type 1 disorders are inexorably progressive, without remissions or exacerbations. Another form (type 2) has normal nerve conduction velocity and is considered an axonal neuropathy without demyelination. Both types 1 and 2 are inherited as autosomal dominant diseases.

In the 1990s the genetic defects in these conditions began to be localized. The type 1 disease was attributed to mutations on two different chromosomes (locus heterogeneity). A more common form (type 1A) was linked to chromosome 17, whereas a less common form (1B) was localized to chromosome 1. To a remarkable degree the genes at these loci have been directly implicated in myelin physiology (Figure 14–3). Type 1A involves a defect in peripheral myelin protein 22, and type 1B the myelin protein P₀. Moreover, as discussed in Chapter 8, an X-linked form of demyelinating neuropathy occurs because of mutations in the gene expressing connexin-32, a subunit of the gap-junction channels that interconnect myelin folds near the nodes of Ranvier (Figure 14–3B). Still other genes have been implicated in inherited demyelination.

Some proteins implicated in axonal neuropathies are identified in Figure 14–4 and Table 14–1. Genes encoding the neurofilament light subunit and an axonal motor protein related to kinesin, which is important for transport along microtubules, are mutated in two types of axonal neuropathies. Defects in these genes are associated with peripheral neuropathies with prominent weakness. The mechanisms by which genes alter axonal function in other axonal neuropathies are less evident.

As noted earlier, a wide range of problems other than genetic mutations lead to peripheral neuropathies. Particularly striking are nerve defects associated with the presence of autoantibodies directed against ion channels in distal peripheral nerves. For example, some individuals with motor unit instability (cramps and fasciculations), as well as sustained or exaggerated muscle contractions caused by hyperexcitability of motor nerves, have serum antibodies directed against one or more axonal voltage-gated K⁺ channels. The prevailing view is that binding the autoantibodies to the channels reduces K⁺ conductance and thereby depolarizes the axon, leading to augmented and sustained firing of the distal motor nerve and associated muscle contractions. Alterations in ion channel function underlie a variety of neurological disorders, as

in acquired disorders of channels in the neuromuscular junction and inherited defects in voltage-gated channels in muscle (discussed below).

Diseases of the Neuromuscular Junction Have Multiple Causes

Many diseases involve disruption of chemical transmission between neurons and their target cells. By analyzing such abnormalities researchers have learned a great deal about the mechanisms underlying normal synaptic transmission as well as disorders caused by dysfunction at the synapse.

Diseases that disrupt transmission at the neuromuscular junction fall into two broad categories:

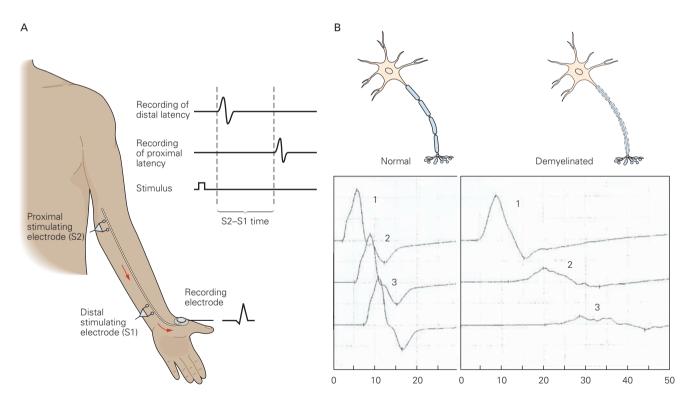

Figure 14–2 Measurement of motor nerve conduction velocity.

A. A shock is applied through a proximal (S2) or distal (S1) stimulating electrode, and the extracellular action potential is measured by the recording electrode. The time it takes the action potential to propagate from S2 to the muscle (t_{S2}) is the proximal latency; the time from S1 to the muscle (t_{S1}) is the distal latency. The distance between S1 and S2 divided by ($t_{S2} - t_{S1}$) gives the conduction velocity.

B. The waveforms of motor nerve action potentials are recorded in the thumb muscles after stimulation of the motor

nerve at the wrist (1), just below the elbow (2), and just above the elbow (3). The action potentials from a normal nerve have the same waveforms regardless of the site of stimulation. They are distinguished only by the longer time period required for the waveform to develop as the site of the stimulus is moved up the arm (away from the recording site). When the motor nerve is demyelinated just distal to the elbow but above the wrist, the motor nerve action potential is normal when stimulation occurs at the wrist (1) but delayed and desynchronized when stimulation is proximal to the nerve lesion (2, 3). (Reproduced, with permission, from Bromberg 2002.)

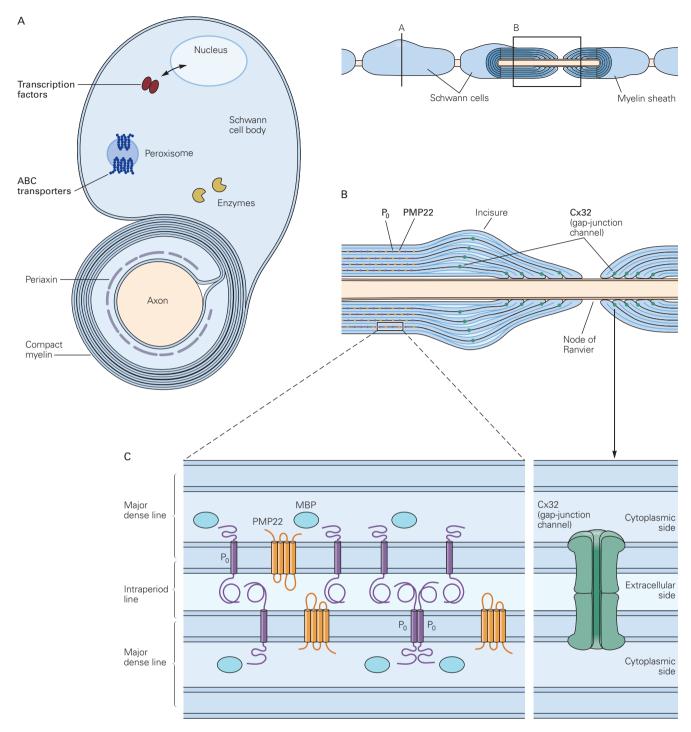

Figure 14–3 Genetic defects in components of myelin cause demyelinating neuropathies.

A. Myelin production and function in the Schwann cell are adversely affected by multiple genetic defects including abnormalities in transcription factors, ABC (ATP-binding cassette) transporters in peroxisomes, and multiple proteins implicated in organizing myelin. In compact myelin thin processes of Schwann cells are tightly wrapped around an axon. Viewed microscopically at high power, the site of apposition of the intracellular faces of the Schwann cell membrane appears as a dense line, whereas the apposed extracellular faces are described as the intraperiod line (see definition in part C). (Adapted, with permission, from Lupiski 1998.)

B. Peripheral axons are wrapped in myelin, which is compact and tight except near the nodes of Ranvier and at focal sites

described as "incisures" by Schmidt and Lanterman. (Adapted, with permission, from Lupiski 1998.)

C. The rim of cytoplasm, in which myelin basic protein (MBP) is located, defines the major dense line, whereas the thin layer of residual extracellular space defines the intraperiod line. Three myelin-associated proteins are defective in three different demyelinating neuropathies: P_0 (Dejerine-Sottas infantile neuropathy), peripheral myelin protein or PMP22 (Charcot-Marie-Tooth neuropathy type 1), and connexin-32 or Cx32 (X-linked Charcot-Marie-Tooth neuropathy). Mutations in PMP22 and P_0 genes adversely affect the organization of compact myelin. (Adapted, with permission, from Brown and Amato 2002.)

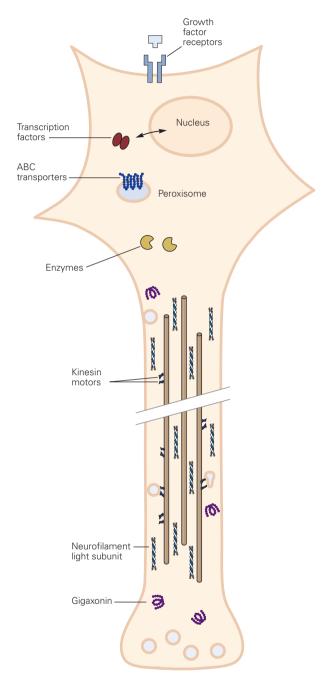

Figure 14–4 Genetic defects in a number of cell constituents cause axonal neuropathies. These include defects in receptors for growth factors, ABC (ATP-binding cassette) transporters in peroxisomes, cytosolic enzymes, microtubule motor proteins like the kinesins, neurofilament proteins, and other structural proteins such as gigaxonin. (Adapted, with permission, from Brown and Amato 2002.)

those that affect the presynaptic terminal and those that primarily involve the postsynaptic membrane. In both categories the most intensively studied cases are autoimmune and inherited defects in critical synaptic proteins.

Myasthenia Gravis Is the Best Studied Example of a Neuromuscular Junction Disease

The most common and extensively studied disease affecting synaptic transmission is myasthenia gravis, a disorder at the neuromuscular junction in skeletal muscle. Myasthenia gravis (the term means severe weakness of muscle) has two major forms. The most prevalent is the autoimmune form. The second is congenital and heritable; it is not an autoimmune disorder and is heterogeneous. Fewer than 500 cases have been identified, but analysis of the congenital syndromes has provided information about the organization and function of the human neuromuscular junction. This form is discussed later in the chapter.

In autoimmune myasthenia gravis antibodies are produced against the nicotinic acetylcholine (ACh) receptor in muscle. These antibodies interfere with synaptic transmission by reducing the number of functional receptors or by impeding the interaction of ACh with its receptors. As a result, communication between the

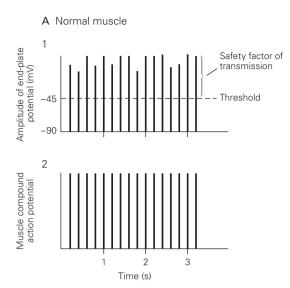

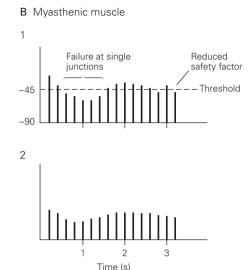

Figure 14–5 Synaptic transmission at the neuromuscular junction fails in myasthenia gravis. (Reproduced, with permission, from Lisak and Barchi 1982.)

A. In the normal neuromuscular junction the amplitude of the end-plate potential is so large that all fluctuations in the potential occur well above the threshold for an action potential. That is, there is a large safety factor in synaptic transmission (1). Therefore, during repetitive stimulation of the motor nerve the amplitude of the compound action potentials, representing the action potentials in all muscle fibers innervated by the nerve, is constant and invariant (2).

motor neuron and the skeletal muscle becomes weakened. This weakness has four special characteristics:

- It almost always affects cranial muscles—eyelids, eye muscles, and oropharyngeal muscles—as well as limb muscles.
- The severity of symptoms varies in the course of a single day, from day to day, or over longer periods (giving rise to periods of remission or exacerbation), making myasthenia gravis unlike most other diseases of muscle or nerve.
- 3. There are no conventional clinical or electromyographic signs of denervation.
- 4. The weakness is reversed by drugs that inhibit acetylcholinesterase, the enzyme that degrades ACh.

Myasthenia gravis is a disorder of neuromuscular transmission. When a motor nerve is stimulated at rates of 2 to 5 per second, the amplitude of the compound action potential evoked in normal human muscle remains constant. In myasthenia gravis the amplitude decreases rapidly. This abnormality

B. In the myasthenic neuromuscular junction postsynaptic changes reduce the amplitude of the end-plate potential so that under optimal circumstances the end-plate potential may be just sufficient to produce a muscle action potential. Fluctuations in transmitter release that normally accompany repeated stimulation now cause the end-plate potential to drop below this threshold, leading to conduction failure at that synapse (1). The amplitude of the compound action potentials in the muscle declines progressively and shows only a small and variable recovery (2).

resembles the pattern induced in normal muscle by *d*-tubocurarine (the active compound in curare), which blocks nicotinic ACh receptors and inhibits the action of ACh at the neuromuscular junction. Neostigmine (Prostigmin), which inhibits acetylcholinesterase and thus prolongs the action of ACh at the neuromuscular junction, reverses the decrease in amplitude of evoked compound action potentials in myasthenic patients (Figure 14–5).

The decrease in the compound muscle action potential in response to repetitive stimulation of the motor nerve mirrors the clinical symptom of fatigability in myasthenia. For example, when patients are asked to look upward in a sustained gaze, the eyelids tire after several seconds and droop downward (ptosis). Like decremental responses on electromyography, this fatigability and drooping reverse after treatment with inhibitors of acetylcholinesterase (Figure 14–6).

Approximately 15% of adult patients with myasthenia have benign tumors of the thymus (thymomas). As the symptoms in myasthenic patients are often improved by removal of these tumors, some element of the thymoma may stimulate autoimmune

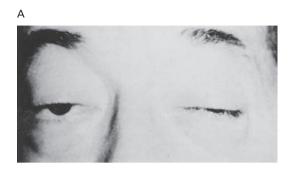

Figure 14–6 Myasthenia gravis often selectively affects the cranial muscles. (Reproduced, with permission, from Rowland, Hoefer, and Aranow 1960.)

A. Severe drooping of the eyelids, or ptosis, is characteristic of myasthenia gravis. This patient also could not move his eyes to look to either side.

B. One minute after an intravenous injection of 10 mg edrophonium, an inhibitor of acetylcholinesterase, both eyes are open and can be moved freely. The inhibition of acetylcholinesterase prolongs the action of ACh in the synaptic cleft, thus compensating for the reduced number of ACh receptors in the muscle (see Figure 14–7).

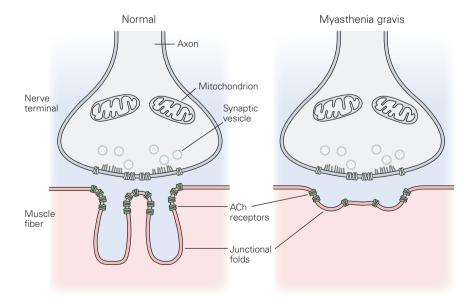

pathology. Indeed, myasthenia gravis often affects people who have other autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythematosus, or Graves disease (hyperthyroidism).

The modern concept of myasthenia emerged with the isolation and characterization of the nicotinic ACh receptor. In 1973 Douglas Fambrough and Daniel Drachman, using radioactive α -bungarotoxin to label the receptor in human end-plates, found fewer binding sites in myasthenic muscle than in controls. In addition, morphological studies revealed a smoothing of the junctional folds, the site of receptor localization (Figure 14–7).

That same year James Patrick and Jon Lindstrom demonstrated in rabbits that the generation of antireceptor antibodies was accompanied by the onset of myasthenia-like symptoms when they injected animals with nicotinic ACh receptors purified from eel electroplax (which is related to the skeletal muscles of higher vertebrates). The weakness was reversed by the cholinesterase inhibitors neostigmine or edrophonium. As in humans with myasthenia gravis, the animals were abnormally sensitive to neuromuscular blocking agents such as curare, and the evoked compound action potentials in muscle decreased with repetitive stimulation. It was later found that a similar syndrome could be induced in mice and other mammals by immunization with nicotinic ACh receptor protein (Figure 14–8).

By 1975 all the essential characteristics of the human disease had been reproduced in experimental

Figure 14–7 Morphological abnormalities of the neuromuscular junction in myasthenia gravis. At the neuromuscular junction ACh is released by exocytosis of synaptic vesicles at active zones in the nerve terminal. Acetylcholine flows across the synaptic cleft to reach receptors that are concentrated at the peaks of junctional folds. Acetylcholinesterase in the cleft rapidly terminates transmission by hydrolyzing ACh. The myasthenic neuromuscular junction has a reduced number of ACh receptors, simplified synaptic folds, and a widened synaptic space, but a normal nerve terminal.

Α

Figure 14–8 The posture of a myasthenic mouse improves after treatment with neostigmine. To produce the syndrome the mouse was immunized with 15 μ g of purified nicotinic ACh receptor protein. (Reproduced, with permission, from Berman and Patrick 1980.)

A. Before treatment the mouse is inactive.

B. The mouse is standing 12 minutes after receiving an intraperitoneal injection of 37.5 μ g/kg neostigmine bromide, which inhibits acetylcholinesterase and thus increases the availability of ACh in the synaptic cleft of the neuromuscular junction.

autoimmune myasthenia gravis in mice, rabbits, and monkeys. After experimental myasthenia gravis was characterized, antibodies directed against nicotinic ACh receptors were found in the serum of many patients with myasthenia. How do these immunological observations account for the characteristic decrease in the response of myasthenic muscle to repeated stimulation?

An action potential in a motor axon normally releases enough ACh to induce a large excitatory endplate potential with an amplitude of approximately 70 to 80 mV relative to the resting potential of –90 mV

(see Chapter 9). Thus the normal end-plate potential is greater than the threshold needed to initiate an action potential, approximately –45 mV. In normal muscle the difference between the threshold and the actual end-plate potential amplitude—the safety factor—is therefore quite large (Figure 14–5A). In fact, in many muscles the amount of ACh released during synaptic transmission can be reduced to as little as 25% of normal before it fails to initiate an action potential.

A reduction in the density of ACh receptors, as in myasthenia, reduces the probability that a molecule of ACh will find a receptor before it is hydrolyzed by the enzyme acetylcholinesterase. In addition, in myasthenia the geometry of the end-plate is also disturbed. The normal infolding at the junctional folds is reduced and the synaptic cleft is enlarged (Figure 14–7). These morphological changes promote diffusion of ACh away from the synaptic cleft and thus further reduce the probability of ACh interacting with the few remaining functional receptors. As a result, the amplitude of the end-plate potential is reduced to the point where it is barely above threshold (Figure 14–5B).

Thus in myasthenia synaptic transmission is readily blocked even though the vesicles in the presynaptic terminals contain normal amounts of ACh and the process of transmitter release is intact. Both the physiological abnormality (the decremental response) and the clinical symptoms (muscle weakness) are partially reversed by drugs that inhibit acetylcholinesterase (Figures 14–6 and 14–8).

How do antibodies cause the symptoms of myasthenia? The antibodies do not simply occupy the site of ACh binding. Rather, they appear to react with epitopes elsewhere on the receptor molecule. This increases the destruction of nicotinic ACh receptors, probably because myasthenic antibodies bind and cross-link the receptors, triggering their degradation (Figure 14–9). In addition, some myasthenic antibodies bind proteins of the complement cascade of the immune system, causing lysis of the postsynaptic membrane.

Despite the evidence documenting the primary role of antibodies against the nicotinic ACh receptor in myasthenia, approximately one-fifth of patients with myasthenia, including some who respond to antimmune therapy like plasmapheresis, do not have these antibodies. Instead, most of these patients have antibodies against another postsynaptic protein, known as MuSK (*muscle-specific Trk-related receptor with a kringle domain*). MuSK is a receptor tyrosine kinase that interacts with agrin, a protein released from the motor nerve terminal that helps to organize the nicotinic ACh receptors into clusters at the neuromuscular junction.

A Normal turnover, 5-7 days B Rapid turnover in myasthenia, 2.5 days Random Receptors collection of ACh aggregated by antibodies receptors Endocytosis by a mechanism that involves cytoskeletal structures and requires energy proteolytic destruction Release of amino acid residue from the cell

Figure 14–9 Turnover of ACh receptors increases in myasthenia. (Adapted, with permission, from Lindstrom 1983, and Drachman 1983.)

A. Normal turnover of randomly spaced ACh receptors takes places every 5 to 7 days.

B. In myasthenia gravis and experimental myasthenia gravis, the cross-linking of ACh receptors by antibodies facilitates endocytosis and the phagocytic destruction of the receptors, which leads to a two- to threefold increase in the rate of receptor turnover. Binding of antireceptor antibody activates the complement cascade, which is involved in focal lysis of the postsynaptic membrane. This focal lysis is probably primarily responsible for the characteristic morphological alterations of postsynaptic membranes in myasthenia (see Figure 14–7).

It appears to be functionally important both during development and in the adult. Although the adverse effects of the anti-MuSK antibodies have not yet been defined, the antibodies block some of the normal clustering of the nicotinic ACh receptors following the interaction of agrin with MuSK.

Treatment of Myasthenia Targets the Physiological Effects and Autoimmune Pathogenesis of the Disease

Anticholinesterases, especially pyridostigmine, provide symptomatic relief, but the treatment is rarely complete and does not alter the basic disease. Immunosuppressive therapies include corticosteroids and azathioprine or related drugs that suppress antibody synthesis.

Plasmapheresis—removing the plasma and the antibodies to the nicotinic ACh receptors or to MuSK—

often ameliorates symptoms within days or a few weeks, as does infusion of immunoglobulin.

Although the benefit is transient, it may be sufficient to prepare a patient for thymectomy or to support the patient through more severe episodes. Intravenous administration of immunoglobulins also reduces the titer of antibodies to the nicotinic ACh receptor and to MuSK by mechanisms that are unclear.

There Are Two Distinct Congenital Forms of Myasthenia Gravis

There are two distinct types of myasthenia in which symptoms may be present from birth. In neonatal myasthenic syndrome the mother herself has autoimmune myasthenia that is transmitted passively to the newborn via the immune system. By contrast, in congenital myasthenia the infant has an inherited defect in some component of the neuromuscular junction,

rather than an autoimmune disease, and thus does not have serum antibodies to the nicotinic ACh receptor or MuSK.

Congenital myasthenic syndromes fall into three broad groups based on the site of the defect in the neuromuscular synapse: presynaptic, synaptic cleft, and postsynaptic forms. Clinical features common to these disorders include a positive family history, weakness with easy fatigability (present since infancy), drooping of the eyelids (ptosis), a decremental response to repetitive stimulation on electromyography, and negative screening for anti-nicotinic ACh receptor antibodies. A striking feature of many of these diseases is the subnormal development of the skeletal muscles, reflecting the fact that normal function at the neuromuscular synapse is required to maintain normal muscle bulk.

In one presynaptic form of congenital myasthenia the enzyme choline acetyltransferase is absent or reduced in the distal motor terminal. This enzyme is essential for the synthesis of ACh from choline and acetyl coenzyme A (see Chapter 13). In its absence the synthesis of ACh is impaired. The result is weakness that usually begins in infancy or early childhood. In another presynaptic form of congenital myasthenia the number of quanta of ACh released after an action potential is less than normal. The molecular basis for this defect is unknown.

Congenital myasthenia may also result from the absence of acetylcholinesterase in the synaptic cleft. In this circumstance end-plate potentials and miniature end-plate potentials are not small, as in autoimmune myasthenia, but are rather markedly prolonged, which may explain the repetitive response of the evoked muscle potential in those patients. Cytochemical studies indicate that ACh-esterase is absent from the basement membranes. At the same time, nicotinic ACh receptors are preserved.

The physiological consequence of ACh-esterase deficiency is sustained action of ACh on the end-plate and ultimately the development of an end-plate myopathy. This myopathy indicates that skeletal muscle can react adversely to excessive electrical stimulation at the neuromuscular junction. In treating this disorder it is critical to avoid using agents like inhibitors of AChesterase that can increase firing in the end-plate and thereby exacerbate the muscle weakness.

Most congenital myasthenia cases are caused by primary mutations in the genes encoding different subunits of the nicotinic ACh receptor. The *slow channel syndrome* is characterized by prominent limb weakness but little weakness of cranial muscles (the reverse of the pattern usually seen in autoimmune myasthenia, where muscles of the eyes and oropharynx are almost

always affected). End-plate currents are slow to decay and channel opening is abnormally long. The mutations probably act both by increasing the affinity of the nicotinic ACh receptor for ACh, thereby prolonging the effects of this transmitter, and by directly slowing the channel closing rate. In some instances quinidine is effective therapy for slow channel syndrome because it blocks the open receptor-channel. As in ACh-esterase mutations, the end-plate degenerates because of excessive postsynaptic stimulation, and thus anticholinesterase medications are potentially dangerous.

In the *fast channel syndrome* a different set of mutations in one or more subunits of the nicotinic ACh receptor leads to an accelerated rate of channel closing and end-plate current decay. The fast channel syndrome may respond either to acetylcholinesterase inhibitors or to 3,4-diaminopyridine, which increases presynaptic firing and ACh quantal release, probably by blocking a presynaptic K⁺ conductance.

Lambert-Eaton Syndrome and Botulism Are Two Other Disorders of Neuromuscular Transmission

Some patients with cancer, especially small-cell cancer of the lung, have a syndrome of proximal limb weakness and a neuromuscular disorder with characteristics that are the opposite of those seen in myasthenia gravis. Instead of a decline in synaptic response to repetitive nerve stimulation, the amplitude of the evoked potential increases; that is, neuromuscular transmission is facilitated. The first postsynaptic potential is abnormally small, and subsequent responses increase in amplitude so that the final summated potential is two to four times the amplitude of the first potential.

This disorder, *Lambert-Eaton syndrome*, is attributed to the action of antibodies against voltage-gated Ca²⁺ channels in the presynaptic terminals. It is thought that these antibodies react with an antigen in the channels, degrading the channels as the antibody-antigen complex is internalized. Calcium channels similar to those in presynaptic terminals are found in cultured cells from the small-cell carcinoma of the lung; development of antibodies against these antigens in the tumor might be followed by pathogenic action against nerve terminals, another kind of molecular mimicry.

A facilitating neuromuscular block also occurs in human botulism, because the botulinum toxin also impairs release of ACh from nerve terminals. Both botulism and Lambert-Eaton syndrome are ameliorated by administration of calcium gluconate or guanidine, agents that promote the release of ACh. These drugs are less effective than immunosuppressive treatments for long-term control of Lambert-Eaton syndrome, which is chronic. However, botulism is transient, and if the patient is kept alive during the acute phase by treating symptoms, the disorder disappears in weeks as the infection is controlled and botulinum toxin is inactivated.

Diseases of Skeletal Muscle Can Be Inherited or Acquired

The weakness seen in any myopathy is usually attributed to degeneration of muscle fibers. At first the missing fibers are replaced by regeneration of new fibers. Ultimately, however, renewal cannot keep pace and fibers are lost progressively. This leads to compound potentials of brief duration and reduced amplitude in the motor unit. The decreased number of functioning muscle fibers accounts for the diminished strength. Skeletal muscle diseases are conveniently divided into those that are inherited and those that appear to be acquired.

Dermatomyositis Exemplifies Acquired Myopathy

The prototype of an acquired myopathy is dermatomyositis, defined by two clinical features: rash and myopathy. The rash has a predilection for the face, chest, and extensor surfaces of joints, including the fingers. The myopathic weakness primarily affects proximal limb muscles. Both rash and weakness usually appear simultaneously and become worse in a matter of weeks. The weakness may be mild or life-threatening.

This disorder affects children or adults. Approximately 10% of adult patients have malignant tumors. Although the pathogenesis is unknown, dermatomyositis is thought to be an autoimmune disorder of small intramuscular blood vessels.

Muscular Dystrophies Are the Most Common Inherited Myopathies

The best-known inherited muscle diseases are the muscular dystrophies; several major types are distinguished by clinical and genetic patterns. Some types are characterized by weakness alone (Duchenne, facioscapulohumeral and limb girdle dystrophies); others have additional clinical features (such as the myotonic muscular dystrophies). Most are recessively inherited and begin in early childhood (Duchenne, Becker, and limb girdle dystrophy); less frequently, the dystrophies are dominantly inherited (facioscapulohumeral or myotonic dystrophy). In the limb-girdle dystrophies

progressive weakness of the proximal limbs is a cardinal trait. In the myotonic muscular dystrophies progressive weakness is accompanied by severe muscle stiffness.

Duchenne muscular dystrophy affects only males because it is transmitted as an X-linked recessive trait. It starts in early childhood and progresses relatively rapidly, so patients are in wheelchairs by age 12 years and usually die in their third decade. This dystrophy is caused by mutations that severely reduce levels of dystrophin, a skeletal muscle protein that apparently confers tensile strength to the muscle cell. In a related inherited muscle disorder known as *Becker muscular dystrophy*, dystrophin is present but is either abnormal in size or reduced in quantity (approximately 10%). Becker dystrophy is thus much milder; individuals with Becker dystrophy typically are able to walk well into adulthood, albeit with weakness of the proximal leg and arm muscles.

The dystrophin gene is the second largest human gene, spanning approximately 2.5 million base pairs, or 1% of the X chromosome and 0.1% of the total human genome. It contains at least 79 exons that encode a 14-kb mRNA. The inferred amino acid sequence of the dystrophin protein suggests a rod-like structure and a molecular weight of 427,000, with domains similar to those of two cytoskeletal proteins, alpha-actinin and spectrin. Dystrophin is localized to the inner surface of the plasma membrane. The amino terminus of dystrophin is linked to cytoskeletal actin, whereas the carboxy terminus is linked to the extracellular matrix by transmembrane proteins (Figure 14–10).

Most boys with Duchenne muscular dystrophy have a deletion in the dystrophin gene; approximately a third have point mutations. In both cases the mutations introduce premature stop codons in the mutant RNA transcripts that prevent synthesis of full-length dystrophin. Becker dystrophy is also caused by deletions and missense mutations, but the mutations do not introduce stop codons. The resulting dystrophin protein is nearly normal in length and can at least partially substitute for normal dystrophin (Figure 14–11).

The discovery of the affected gene product in Duchenne muscular dystrophy by Louis Kunkel in the mid-1980s was rapidly followed by the discovery of numerous other novel muscle proteins, some with an intimate relationship to dystrophin. As a result, the primary genetic and protein defects underlying most major muscular dystrophies have now been identified (Table 14–2). Thus it may be more constructive now to change the system of classifying the dystrophies to one based on the component of the muscle cell that is implicated. Most of the dystrophies, best represented

LGMD, limb-girdle muscular dystrophy.

by dystrophin deficiency, are believed to arise because of accelerated muscle injury and breakdown. A small group, associated with deficiency of the protein dysferlin, is a consequence of slower repair of muscle membrane after injury (Figure 14–10).

Many of these disorders are characterized by slowly progressive weakness of the proximal arms and legs and thus are limb-girdle dystrophies. Most are recessively inherited; mutations in both copies of a particular gene prevent expression of the normal protein product and thus lead to loss of function of that protein.

Primary genetic defects in a diverse group of skeletal muscle proteins lead to the limb-girdle phenotype (Table 14–2) in which weakness is prominent in the torso and in proximal muscles of the arms and legs. Why this pattern of degeneration is so common is unknown, especially because the affected proteins are expressed in both distal and proximal muscles. The pattern likely reflects muscle use. The proximal muscles are, on average, more subject to low-level but chronic contractile activity because they serve as antigravity muscles.

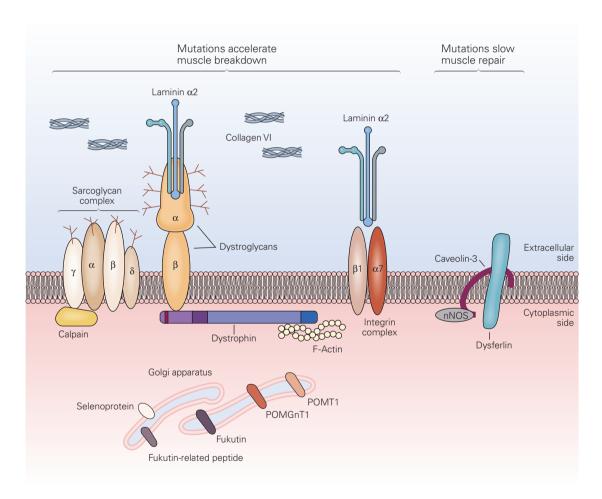

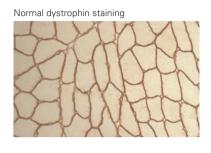

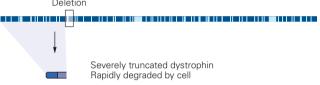

Figure 14–10 In muscular dystrophy mutant proteins either weaken the muscle cell membrane or slow its repair after injury. For example, a deficiency of dystrophin, a submembrane protein, causes Duchenne muscular dystrophy. Dystrophin interacts with complexes of other membrane proteins that are mutant in other dystrophies, including the dystroglycans and the sarcoglycans, which are closely associated with extracellular proteins such as laminin $\alpha 2$ and collagen. Several other proteins that are normally present in

the Golgi apparatus and essential for adding sugar groups to membrane proteins are found to be mutant in different forms of muscular dystrophy. These include POMT1 (protein $\emph{O}\text{-}\text{mannosyl}$ transferase 1), POMGnT1 (protein $\emph{O}\text{-}\text{mannosyl}$ $\beta1,2-\emph{N}\text{-}\text{acetylglucosaminyl}$ transferase), fukutin, fukutin-related peptide, and a selenoprotein. Dysferlin, which is mutated in still other dystrophies, is involved in the repair of skeletal muscle membrane after injury. (Modified, with permission, from Brown and Mendell 2005.)

2 Deletion of four exons results in milder (Becker) dystrophy

Dystrophin staining in Becker dystrophy

Figure 14–11 Two forms of muscular dystrophy are caused by deletion mutations in the dystrophin gene. (Adapted, with permission, from Hoffman and Kunkel 1989; photos, reproduced with permission, from Arthur P. Hays.)

A. The relative position of the dystrophin gene within the Xp21 region of the X chromosome. An enlargement of this locus shows the 65 exons (**light blue**) and introns (**dark blue**) defining the gene with approximately 2.0×10^6 base pairs. Transcription of the gene gives rise to mRNA (approximately 14×10^3 base pairs), and translation of this mRNA gives rise to the protein dystrophin (mol wt 427,000). Expression of dystrophin in a normal muscle is shown in an immunoperoxidase stain photo at right.

B. A deletion of genomic DNA encompassing only a single exon results in the clinically severe Duchenne muscular dystrophy. A larger deletion encompassing four exons results in the clinically milder Becker muscular dystrophy. In both cases the gene is transcribed into mRNA, and the exons flanking the

deletion are spliced together. 1. If a single exon is deleted and a nonintegral set of codons is missing, the borders of neighboring exons may not match, causing the translational reading frame to shift. As a result, incorrect amino acids are inserted into the growing polypeptide chain until an abnormal stop codon is reached, causing premature termination of the protein. The truncated protein may be unstable, may fail to be localized in the membrane, or may fail to bind to glycoproteins. Functional dystrophin is then almost totally absent. A muscle biopsy of Duchenne dystrophy (right) shows no detectable immunoreactive dystrophin. 2. If the deletion is larger but an integral number of codons are deleted, the reading frame can be maintained in the mRNA. This produces a dystrophin molecule with an internal deletion but intact ends. Although the protein is smaller than normal and may be present in less than normal amounts, some muscle function is preserved. Immunoperoxidase staining of dystrophin is minimally reduced in a muscle biopsy of Becker dystrophy (right).

Myotonic dystrophy has several distinctive features, including an autosomal inheritance pattern, weakness that is predominantly distal, involvement of nonmuscle tissues, and striking muscle stiffness (myotonia). The stiffness is induced by excessive electrical discharges of the muscle membrane associated with voluntary muscle contractions or percussive or electrical stimulation of the muscle. It is most intense with the first few movements after a period of rest and improves with continued muscular activity (*warm-up* phenomenon). Typical features are difficulty relaxing the grip of a handshake for several seconds, difficulty opening the eyelids after forceful squinting, or stiffness in the legs with the first few steps after rising from a chair.

Electromyography demonstrates that the muscle cell membrane is electrically hyperexcitable; after a contraction, bursts of repetitive action potentials wax and wane in amplitude and frequency (20–100 Hz) over several seconds and thereby delay relaxation (Figure 14–12A). This sustained contraction is truly independent of nerve supply because it persists after blockade of either the incoming motor nerve impulse or neuromuscular transmission with agents such as curare.

The symptoms are not confined to muscles. Almost all patients have cataracts; affected men commonly have testicular atrophy and baldness and often develop cardiac conduction system defects that lead to irregularities in the heartbeat. The primary genetic defect is a dominantly transmitted expansion of a triplet of base pairs (CTG) in a noncoding region of a gene (myotonin kinase) on chromosome 19. RNA transcripts of the expanded CTG segments accumulate in the nucleus and alter splicing of several critical genes, including the gene for a Cl⁻ channel, ClC-1 (see Chapter 5). Loss of function of this channel leads to excessive electrical activity in skeletal muscle and, as a consequence, myotonia. As discussed below, direct mutations in the same Cl⁻ channel gene can lead to a similar abnormal pattern of muscle activity.

Some Inherited Diseases of Skeletal Muscle Arise from Genetic Defects in Voltage-Gated Ion Channels

The normal electrical excitability of skeletal muscle is essential to the rapid and nearly synchronous contraction of an entire muscle fiber. The depolarizing end-plate potential at the neuromuscular junction triggers an action potential that propagates longitudinally along the surface of the muscle fiber and radially inward along the transverse tubules, invaginations of the fiber membrane that come into close apposition with the sarcoplasmic reticulum (see Chapter 34).

Depolarization of the transverse tubules induces a conformational change in L-type voltage-gated Ca²⁺ channels. The conformational change is directly transmitted to a particular class of Ca²⁺ release channels (ryanodine receptors) in the sarcoplasmic reticulum, causing the channels to open. The release of Ca²⁺ from the sarcoplasmic reticulum raises myoplasmic Ca²⁺ and thus activates ATP-dependent movement of actin-myosin filaments.

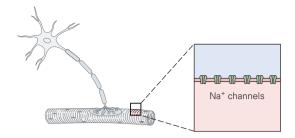

Normally, one action potential is generated in a muscle fiber for each end-plate potential. Repolarization of the muscle action potential depends on inactivation of Na⁺ channels and the opening of delayed-rectifier voltage-gated K⁺ channels similar to those in axons. In addition, Cl⁻ influx through the ClC-1 channels is important in maintaining the normal negative resting potential. Mutations in any one of these channels contribute to inherited muscle disease.

Periodic Paralysis Is Associated with Altered Muscle Excitability and Abnormal Levels of Serum Potassium

The electrical coupling of the end-plate potential to depolarization of the transverse tubules is disrupted in several inherited diseases of muscle. These disorders reflect a variety of defects in excitability ranging from complete failure of action potential generation to prolonged bursts of repetitive discharges in response to a single stimulus (Figure 14–12). The derangements of muscle fiber excitability are transient and result in *periodic paralysis*. Between episodes muscle function is normal. These are rare diseases of skeletal muscle, with a prevalence of 1 per 100,000 or less. Inheritance is autosomal dominant, except for one form of myotonia.

Weakness may be so severe during an attack of periodic paralysis that a patient is bedridden for hours, unable to raise an arm or leg off the bed. Fortunately, during such attacks the muscles of respiration and swallowing are spared, so life-threatening respiratory arrest does not occur. Attack frequency is variable from almost daily to only a few episodes in a lifetime. Consciousness and sensation are not impaired.

During an attack the resting potential of affected muscles is depolarized from a normal value of –90 mV to approximately –60 mV. At this depolarized potential most Na⁺ channels are inactivated, rendering the muscle fiber chronically refractory and thus unable to generate action potentials. Recovery of strength occurs spontaneously and is associated with repolarization to a resting potential within a few millivolts of normal and recovery of excitability.

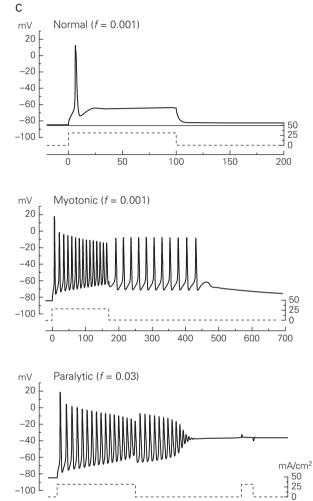

Figure 14–12 Myotonia or paralysis may result from impaired inactivation of Na⁺ channels in skeletal muscle.

A. The electrical signature of myotonia (muscle stiffness) is a rapid burst of action potentials in response to a single stimulus. The action potentials, shown here from extracellular recordings, vary in amplitude and wax and wane in frequency. Such a burst may be triggered by a voluntary muscle contraction or a mechanical stimulus such as percussion of the muscle.

B. Cell-attached patch recordings from cultured human muscle cells. In normal muscle the Na⁺ channels open early and briefly in response to a voltage-clamp depolarization from –120 mV to –40 mV. In muscle from patients with hyperkalemic periodic paralysis (M1592V Na⁺ channel mutation) the prolonged openings and reopenings indicate impaired inactivation. The

probability of channel opening (obtained by averaging individual records) remains elevated in the hyperkalemic muscle following inactivation. (Reproduced, with permission, from Cannon, Brown, and Corey 1991.)

C. Even modest disruption of Na^+ channel inactivation is sufficient to produce bursts of myotonic discharges or depolarization-induced loss of excitability. These computer simulation records show muscle voltage in response to an injected depolarizing current (dashed line). The fraction of mutant channels that actually fails to inactivate normally (f) varies within a population over time. In these simulations f was varied from normal to values appropriate for myotonic or paralytic muscle. (Reproduced, with permission, from Cannon, Brown, and Corey 1993.)

Two variants of periodic paralysis have been delineated. Hyperkalemic periodic paralysis attacks occur during periods of high venous K^+ (6.0 mM or higher versus normal levels of 3.5–4.5 mM). Ingesting foods with high K^+ content such as bananas or fruit juice may trigger an attack. Conversely, hypokalemic periodic paralysis presents as episodic weakness in association with low blood K^+ (2.5 mM or lower). Affected muscle is paradoxically depolarized in the setting of reduced extracellular K^+ , which shifts the reversal potential for K^+ to more negative values. Both forms are inherited as autosomal dominant traits.

Genetic analyses have demonstrated that hyperkalemic periodic paralysis is caused by missense mutations in a gene that encodes the pore-forming subunit of a voltage-gated Na+ channel expressed in skeletal muscle. Inactivation of mutant Na⁺ channels is disrupted. Subtle defects of inactivation produce myotonia; more pronounced changes result in chronic depolarization and loss of excitability with paralysis (Figure 14–12B, C). Hypokalemic paralysis is usually caused by mutations in a gene that encodes the main subunit of a voltagesensitive Ca²⁺ channel in skeletal muscle. Andersen's syndrome, a rare form of periodic paralysis characterized by weakness, developmental defects, and cardiac irritability, is caused by primary mutations in the gene for an inward-rectifying K⁺ channel important for establishing the resting potential (Figure 14–13).

In myotonia congenita muscle stiffness is present from birth and is not progressive. Unlike myotonic dystrophy there is no muscle wasting, permanent muscle weakness, or other organ involvement. Myotonia congenita is a consequence of mutations in the gene coding for the ClC-1 Cl⁻ channel in skeletal muscle membrane. The resultant decrease in Cl⁻ influx leads to membrane depolarization and repetitive firing. The disease is inherited as a dominant, semidominant, or recessive trait.

An Overall View

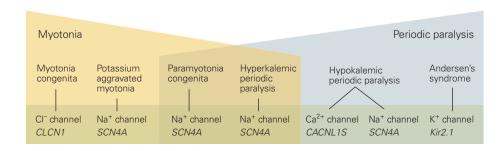

Studies of the diseases of the peripheral nervous system represent a powerful synergy between clinical and basic neuroscience and the fruitful interaction of both approaches with molecular genetics and molecular immunology. Progress in the last decade in defining the molecular basis for these disorders has been extraordinary. Molecular genetic analyses of most disorders inherited as Mendelian traits, beginning only with clinical data in affected families and DNA from family members, have led to the description of causative defects in muscle and nerve proteins.

In some diseases, such as primary muscular dystrophies and inherited neuropathies, little is known about the normal function of the newly discovered disease genes. Thus, the investigation of these diseases has generated new opportunities to learn about the basic molecular and cellular biology of nerve and muscle. In other diseases, such as familial amyotrophic lateral sclerosis and the ion channel diseases, the disease genes and proteins have previously been identified and studied extensively; there is already a large body of biological and biophysical information on which to base further studies.

Also remarkable is the convergence of the discovery of the primary gene defects in the inherited nerve and muscle disorders with new technologies for manipulating the DNA of mice. We now have mouse models of the human diseases with precisely defined genetic defects (using transgenes to over express specific mutant proteins or gene knock-out technology to disrupt the function of proteins). These are already proving invaluable for the analysis of the function of novel proteins, the mechanism of disease evolution, and studies of new treatment strategies.

In general, the development of new therapies for these disorders has lagged behind discovery of

Figure 14–13 The myotonias and periodic paralyses are caused by mutations in genes for diverse voltage-gated ion channels in the skeletal muscle membrane. Some channel disorders are characterized only by myotonia, some only by periodic paralysis, and some by myotonia and paralysis. Some clinical disorders (eg, hypokalemic periodic paralysis) may arise from defects in different channels in different individuals.

the offending genetic or immune defects. The best exception to this generalization is myasthenia gravis; anti-immune therapies have dramatically reduced myasthenia mortality. Converting new molecular insights from other neuromuscular diseases into effective treatments will be a central challenge for clinical neuroscience in the next decade.

The primary therapy for recessively inherited, loss-of-function diseases will ultimately be some form of replacement of the missing protein; the use of viral-mediated gene therapy has already been explored in a pilot study of adults with a sarcoglycan deficiency. It is conceivable that newer methods to replace the missing proteins will not require viral delivery systems.

A major therapeutic challenge across all of human genetics is how to treat the dominantly inherited diseases in which the primary pathology involves cytotoxic effects of the gene mutations. Exciting strategies are evolving to inactivate the mutant allele. These include developing small molecules and proteins that inactivate the promoters for the genes and infusing either antisense oligonucleotides or inhibitory RNA molecules to inactivate the RNA templates made from the genes. Moreover, as the cellular pathways activated by the mutant genes and proteins become known, more downstream targets for the development of more conventional drug therapies will be identified.

For all these reasons we can be optimistic that the molecular analysis of these neuromuscular disorders will continue to illuminate important neurobiological principles in the neuromuscular system while at the same time opening new avenues for primary treatments of these often devastating diseases.

Postscript: Diagnosis of Motor Unit Disorders Is Aided by Laboratory Criteria

When the sole manifestation of a disease is limb weakness (with no fasciculation or upper motor neuron signs) clinical criteria may be insufficient to distinguish neurogenic and myopathic diseases. To assist in this differentiation, clinicians rely on several laboratory tests: measurement of muscle enzyme activity in serum, electromyography and nerve conduction studies, muscle biopsy, and DNA analysis.

One test that helps distinguish myopathic from neurogenic diseases is the measurement of serum enzyme activities. The sarcoplasm of muscle is rich in soluble enzymes that are normally found in low concentrations in the serum. In many muscle diseases the concentration of these sarcoplasmic enzymes in serum is elevated, presumably because the diseases affect the integrity of

surface membranes of the muscle that ordinarily keep soluble enzymes within the sarcoplasm. The enzyme activity most commonly used for diagnosing myopathy is creatine kinase, an enzyme that phosphorylates creatine and is important in the energy metabolism of muscle.

Some abnormalities can be diagnosed by electromyography, a clinical procedure in which a small needle is inserted into a muscle to record extracellularly the electrical activity of several neighboring motor units. Three specific measurements are important: spontaneous activity at rest, the number of motor units under voluntary control, and the duration and amplitude of action potentials in each motor unit.

In normal muscle there is usually no activity outside the end-plate in the muscle at rest. During a weak voluntary contraction a series of motor unit potentials is recorded as different motor units become recruited. In fully active normal muscles these potentials overlap in an interference pattern so that it is impossible to identify single potentials (Figure 14–14A). Normal values have been established for the amplitude and duration of motor unit potentials. The amplitude of the motor unit potential is determined by the number of muscle fibers within the motor unit.

In neurogenic disease the partially denervated muscle is spontaneously active even at rest. The muscle may still contract in response to voluntary motor commands; but because some motor axons have been lost, the number of motor units under voluntary control is smaller than normal. During a maximal voluntary contraction the loss of motor units is evident in the EMG, which shows a discrete pattern of motor unit potentials instead of the profuse interference pattern for normal muscles (Figure 14–14B).

In recently denervated muscle the EMG may also show fibrillation potentials, low-amplitude electrical potentials that correspond to the firing of a single muscle fiber. As the neurogenic disease progresses, the amplitude and duration of individual motor unit potentials may increase, because the remaining axons give off small branches that innervate the muscle fibers denervated by the loss of other axons. Accordingly, surviving motor units contain more than the normal number of muscle fibers.

In myopathic diseases there is no activity in the muscle at rest and no change in the number of motor units firing during a contraction. But because there are fewer surviving muscle fibers in each motor unit, the motor unit potentials are of shorter duration and smaller in amplitude (Figure 14–14C).

The conduction velocities of peripheral motor axons can also be measured through electrical stimulation and recording (see Figure 14–2). The conduction

velocity of motor axons is slowed in demyelinating neuropathies but is normal in neuropathies without demyelination (axonal neuropathies).

The histochemical appearance of muscle in a biopsy can provide a useful diagnostic tool. Human muscle fibers are identified by histochemical reactions as type I or type II, which respectively are either aerobic (enriched for oxidative enzymes) or anaerobic (abundant glycolytic enzymes) (see Chapter 34). All muscle fibers innervated by a single motor neuron are of the

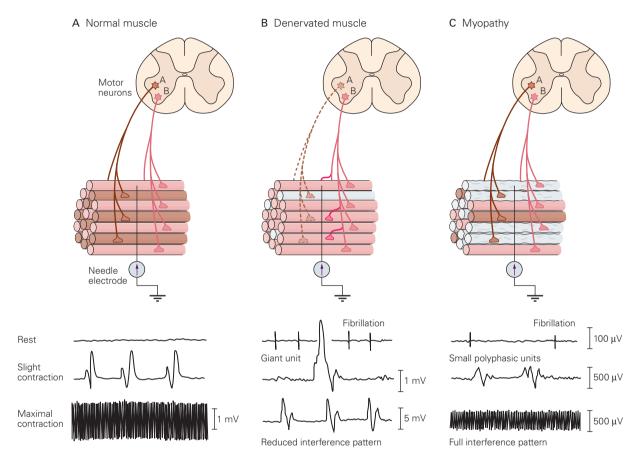

Figure 14–14 Neurogenic and myopathic diseases have different effects on the motor unit.

A. A motor unit potential is recorded by inserting a needle electrode into the muscle. The muscle fibers innervated by a single motor neuron are not usually adjacent to one another, yet the highly effective transmission at the neuromuscular junction ensures that each muscle fiber innervated by the same neuron will generate an action potential and contract in response to an action potential in the motor neuron. Activation of one or a few motor neurons produces a simple extracellular voltage signal and a small contraction (middle trace). A larger contraction activates a greater number of motor neurons and a larger number of muscle fibers, producing a strong contraction (lower trace). The extracellular voltage signal is more complex. Interference from the extracellular currents through the large number of muscle fibers, which are activated at slightly different times by the large number of motor neurons.

B. When motor neurons are diseased, the number of motor units under voluntary control is reduced. The muscle fibers

supplied by the degenerating motor neuron (cell A) become denervated and atrophic. However, the surviving neuron (cell B) sprouts axonal branches that reinnervate some of the denervated muscle fibers. The electromyogram shows larger than normal motor unit potentials (middle trace) because the surviving motor neuron innervates more than the usual number of muscle fibers (it also innervates formerly denervated fibers). Axons of the surviving motor neuron fire spontaneously even at rest, giving rise to fasciculations, another characteristic of motor neuron disease. Single denervated fibers also fire spontaneously, producing fibrillations (top trace). Under conditions of maximal contraction the interference pattern is reduced (lower trace) because muscle fiber action potentials are more synchronized due to the reduced number of motor neuron inputs.

C. When muscle is diseased the number of muscle fibers in each motor unit is reduced. Some muscle fibers innervated by the two motor neurons shrink and become nonfunctional. In the electromyogram the motor unit potentials do not decrease in number but are smaller and of shorter duration than normal.

same histochemical type. However, the muscle fibers of one motor unit are normally interspersed among the muscle fibers of other motor units. Enzyme stains of a cross section of healthy muscle show that oxidative or glycolytic fibers are intermixed in a *checkerboard* pattern.

In chronic neurogenic diseases the muscle innervated by a dying motor neuron becomes atrophic and some muscle fibers disappear. Axons of surviving neurons tend to sprout and reinnervate some of the nearby remaining muscle fibers. Because the motor neuron determines the biochemical properties of a muscle fiber, the reinnervated muscle fibers assume the histochemical properties of the innervating neuron. As a result, the fibers of a muscle in neurogenic disease become clustered by type (a pattern called *fiber-type grouping*).

If the disease is progressive and the neurons in the surviving motor units also become affected, atrophy occurs in groups of adjacent muscle fibers belonging to the same histochemical type, a process called *group atrophy*. In contrast, the muscle fibers in myopathic

diseases are affected in a more or less random fashion. Sometimes an inflammatory cellular response is evident and sometimes there is prominent infiltration of the muscle by fat and connective tissue.

The main clinical and laboratory features used for the differential diagnosis of diseases of the motor unit are listed in Table 14–3.

Part IV

Preceding Page A crowd watches a tightrope walker. The specific movements and perilous position of the acrobat are thought to resonate with viewers by engaging their system of mirror neurons. These neurons are activated both when an individual performs a set of movements, and when he or she observes those same movements performed by others. Similar neural systems may underlie social cognition as well, allowing us to perceive and comprehend the mental states of others. (Reproduced, with permission, from Arthur Paxton.)

IV

The Neural Basis of Cognition

So far in this book we have examined the properties of individual nerve cells and how they communicate at synapses to produce simple reflex behaviors. We now begin to consider larger, interconnected networks of neurons, the complex circuits that give rise to mental activity: perception, planned action, and thought. The field of systems neuroscience aims to understand how these networks produce the cognitive functions of the brain, one of the ultimate challenges of science. We need to know how sensory information is perceived, and how perceptions are assembled into inner representations and recruited into plans for immediate behavior or concepts for future actions. It is still unclear how complex memories are made and how percepts, ideas, and feelings are transformed into language.

Neural science first emerged in the mid-1950s with the development of powerful techniques for exploring the cellular dynamics of the nervous system and with the convergence into a single discipline of several previously separate disciplines concerned with the brain and behavior: molecular biology, neuroanatomy, electrophysiology, and cell and developmental biology. The modern science of mind is the pragmatic result of the attempt to merge neural science with cognitive psychology. New techniques permit us to observe the system properties of the brain directly, not only in animal models, but in controlled behavioral experiments in alert, behaving people. As a result neural science is able to address testable hypotheses about how brain functions lead to mental processes such as perception, memory, decisions, and actions.

The aim of the new science of mind is to examine classical philosophical and psychological questions about mental functions in the light of modern cell and molecular biology. This is a bold undertaking. How do we begin to think about perception, ideas, action, and feelings in biological terms? So far, progress in understanding the major functional systems of the brain—the sensory, motor, motivational, memory, and attentional systems—has benefited from a reductionist approach to mental function. This approach is based on the assumption that these functions will emerge from the biological properties of nerve cells and of their pattern of interconnections. According to this view, which was introduced in Chapter 1, brain and mind are

inseparable. Mind can be considered a set of operations carried out by the brain, an information-processing organ made powerful by the enormous number, variety, and interactions of its nerve cells and by the complexity of interconnection among these cells. In this section and later parts of this book, we describe the attempt to extend this cell biological approach beyond the neuron doctrine to the neuronal circuit doctrine, to the cognitive functions of the brain. We focus specifically on the major domains of cognitive neural science: perception, action, motivation, attention, learning, and memory.

An understanding of the biological basis of cognitive functions requires deep appreciation of the anatomy of the neural systems that subserve these functions in the brain. In the same way that the detailed structure of a protein reveals important principles of its action, knowledge of neuroanatomy and physiology can provide profound insight into how the nervous system functions. Just as many contemporary ideas about the dynamic mechanisms underlying the development of connectivity in the nervous system were anticipated a century ago by Ramón y Cajal on the basis of Golgi images of neurons in histological specimens, we predict that much of our understanding of higher brain function will depend on refined mapping of neuronal circuits and analysis of the signals that pass through those circuits.

Modern anatomical, physiological, and imaging techniques are revealing how neural circuits are organized. For example, the sensory pathways from one brain region to the next are organized in such a way that neighboring groups of neurons in the brain maintain the spatial relationship of sensory receptors in the periphery of the body. This topological organization is an important way of conveying spatial information about sensory events. In recent years, the study of connectivity in the brain has been advanced even further with new imaging techniques, such as diffusion-tensor imaging. These techniques have made visible the patterns of interconnectivity of different regions of the living human brain during specific behaviors. As a consequence, a much clearer idea of the brain regions involved in many complex cognitive functions is emerging.

In this part of the book, we first review in Chapters 15 and 16 the anatomical organization of the three major functional subdivisions of the nervous system: sensory, motor, and modulatory. We also take a closer look at the structural and functional organization of the central nervous system by following the flow of sensory information from the periphery into the spinal cord and brain, the transformation of that information into a motor command, and the effect of that command on muscle, the organ of behavior. We then examine in Chapters 17 and 18 the cognitive processes of the brain that are concerned with visual perception, planned action, memory, and selective conscious attention. Many of these activities are represented in higher-order-association regions of the cerebral cortex, areas that bring together information from various sensory systems to provide coordinated plans for action. A number of major insights in action

and perception are now emerging. Perhaps most importantly, we examine in Chapter 19 why we no longer conceive of sensory and motor and cognitive processes as occurring sequentially. Rather perception and the planning for action occur simultaneously, and the higher motor systems have cognitive functions. One of the important questions that we shall examine in this section is how mental functions are represented in different regions of the brain. In doing so we shall explore what approaches can be used to render cognitive processes such as attention, motivation, and even consciousness accessible to rigorous physiological and anatomical analysis.

In later parts of the book we shall explore each functional system of the brain in detail, examining how the specific structure and cellular interconnections of a system determine its particular function.

An Overall View

In the Earlier Chapters of this book we emphasized that modern neuroscience is based importantly on two tenets. First, the brain is organized into functionally specific areas, and second, neurons in different parts of the vertebrate nervous system, indeed in all nervous systems, are quite similar. What distinguishes one functionally distinct brain region from another, and one brain from the next, are the

number and types of neurons in each and how they are interconnected through development. The specific patterns of interconnection and the resulting functional organization of neural circuits in distinct brain regions underlie the individuation of behavior.

All behavior, from simple reflex responses to complex mental acts, is the product of signaling between appropriately interconnected neurons. Consider the simple act of hitting a tennis ball (Figure 15–1). Visual information about the motion of the approaching ball is analyzed in the visual system. This information is combined with proprioceptive information about the position of the arms, legs, and trunk to calculate the movement necessary to intercept the ball. Once the swing is initiated, many minor adjustments of the motor program are made based on a steady stream of sensory information about the trajectory of the approaching ball. Finally, this entire act is accessible to consciousness, and thus may elicit memories and emotions. Of course, as the swing is being executed, the brain is also engaged in maintaining the player's heart rate, respiration, and other autonomic functions that are typically outside the awareness of the player.

Thus, to understand the neural control of any behavior it is necessary to break down that behavior into key components, to then identify the regions of the brain responsible for each component, and to analyze the neural connections between those regions. Although the anatomy of the brain and its interconnections appear complex, brain anatomy is easier to grasp if one understands the relatively simple set of principles that underlie the fundamental organization of the nervous system. In this and the next five

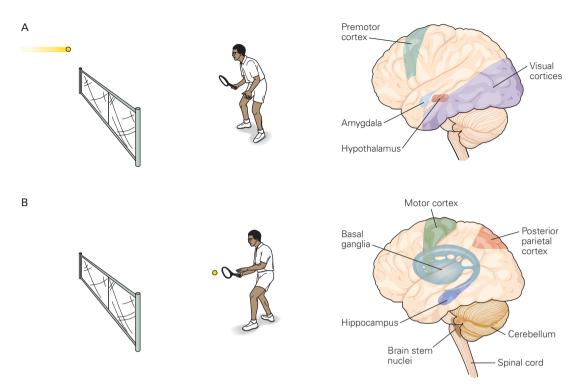

Figure 15–1 A simple behavior is mediated by many parts of the brain.

A. A tennis player watching an approaching ball uses the visual cortex to judge the size, direction, and velocity of the ball. The premotor cortex develops a motor program to return the ball. The amygdala acts in conjunction with other brain regions to adjust the heart rate, respiration, and other homeostatic mechanisms and also activates the hypothalamus to motivate the player to hit well.

B. To execute the shot the player must use all of the structures illustrated in part A as well as others. The motor cortex sends

signals to the spinal cord that activate and inhibit many muscles in the arms and legs. The basal ganglia become involved in initiating motor patterns and perhaps recalling learned movements to hit the ball properly. The cerebellum adjusts movements based on proprioceptive information from peripheral sensory receptors. The posterior parietal cortex provides the player with a sense of where his body is located in space and where his racket arm is located with respect to his body. Throughout the movement, brain stem neurons regulate heart rate, respiration, and arousal. The hippocampus is not involved in hitting the ball but is involved in storing the memory of the return so that the player can brag about it later.

chapters we examine the relationship between anatomy and behavior in a series of progressively more complex examples.

In this chapter and the next we review the major anatomical components of the central nervous system by outlining the organization of the major functional systems that recruit these components. In Chapters 17 and 18 we examine how complex cognitive functions are constructed from the interaction of cortical association areas. In Chapter 19 we describe how in higher cortical association areas perception—the product of the sensory systems—and action—the product of the motor systems—work in parallel. Finally, in Chapter 20 we explore how complex cognitive functions of humans, including attention and consciousness, can be studied by means of brain imaging.

The Central Nervous System Consists of the Spinal Cord and the Brain

The location and orientation of components of the central nervous system within the body are described with reference to three axes: the rostral-caudal, dorsal-ventral, and medial-lateral axes (Figure 15–2).

The spinal cord is the most caudal part of the central nervous system and in many respects the simplest part. It extends from the base of the skull to the first lumbar vertebra. The spinal cord receives sensory information from the skin, joints, and muscles of the trunk and limbs, and contains the motor neurons responsible for both voluntary and reflex movements. Along its length the spinal cord varies in size and shape, depending on whether the emerging motor

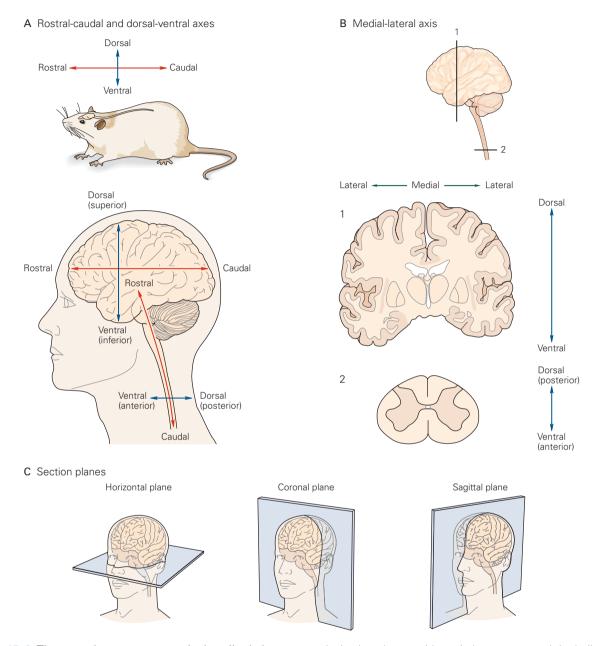

Figure 15–2 The central nervous system is described along three major axes. (Adapted, with permission, from Martin 2003.)

A. Rostral means toward the nose and caudal toward the tail. Dorsal means toward the back of the animal and ventral toward the belly. In lower mammals the orientations of these two axes are maintained through development into adult life. In humans and other higher primates the longitudinal axis flexes in the brain stem by approximately 110°. Because of this flexure the same positional terms have different meanings when referring to structures below and above the flexure. Below the flexure, in the spinal cord, rostral means toward the head, caudal means toward the coccyx (the lower end of the

spinal column), ventral (anterior) means toward the belly, and dorsal (posterior) means toward the back. Above the flexure, rostral means toward the nose, caudal means toward the back of the head, ventral means toward the jaw, and dorsal means toward the top of the head. The term *superior* is often used synonymously with dorsal, and *inferior* means the same as ventral.

B. *Medial* means toward the middle of the brain and *lateral* toward the side.

C. When brains are sectioned for analysis, slices are typically made in one of three cardinal planes: horizontal, coronal, or sagittal.

nerves innervate the limbs or trunk; it is thicker at levels that innervate the arms and legs.

The spinal cord is divided into a core of central gray matter and surrounding white matter. The gray matter, which contains nerve cell bodies, is typically divided into dorsal and ventral horns (so-called because the gray matter appears H-shaped in transverse sections). The dorsal horn contains an orderly arrangement of sensory relay neurons that receive input from the periphery, whereas the ventral horn contains groups of motor neurons and interneurons that regulate motor neuronal firing patterns. The axons of motor neurons innervate specific muscles. The white matter is made up in part of rostral-caudal (longitudinal) ascending and descending tracts of myelinated axons. The ascending pathways carry sensory information to the brain, while the descending pathways carry motor commands and modulatory signals from the brain to the muscles.

The nerve fibers to and from the spinal cord are bundled in 31 spinal nerves, each of which has a sensory and a motor division. The sensory division (the dorsal root) carries information from muscles and skin into the spinal cord and terminates in the dorsal aspect of the cord. Different classes of axons within the dorsal roots convey pain, temperature, touch, and visceral sensory information. The motor division (the ventral root) emerges from the ventral aspect of the cord and comprises the axons of motor neurons that innervate muscles. Ventral roots from certain levels of the spinal cord also include sympathetic and parasympathetic axons. The motor neurons of the spinal cord comprise the "final common pathway" through which all higher brain levels controlling motor activity must act.

The brain, which lies rostral to the spinal cord, is composed of six regions: the medulla, pons, midbrain, cerebellum, diencephalon, and cerebral hemispheres or telencephalon (Figure 15–3). Each of these divisions is found in both hemispheres of the brain with slight bilateral differences. Each of the six divisions is further subdivided into several anatomically and functionally distinct areas.

The three divisions of the central nervous system immediately rostral to the spinal cord—the medulla, pons, and midbrain—are collectively termed the brain stem.

Cerebral cortex

Diencephalon

Midbrain

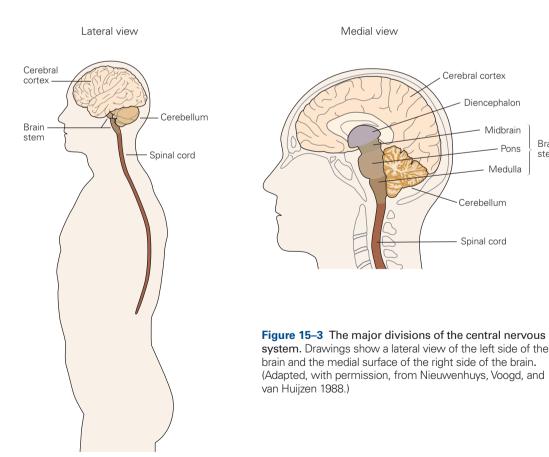

Medulla

Cerebellum

Spinal cord

Pons

Brain

The *medulla*, the most caudal portion of the brain stem, is a direct extension of the spinal cord and resembles the spinal cord both in organization and function. Neuronal groups in the medulla participate in regulating blood pressure and respiration. The medulla also contains neuronal groups that are early components of pathways that mediate taste, hearing, and maintenance of balance as well as the control of neck and facial muscles.

The *pons* lies rostral to the medulla and protrudes from the ventral surface of the brain stem. The ventral portion of the pons contains the pontine nuclei, groups of neurons that relay information about movement and sensation from the cerebral cortex to the cerebellum. The dorsal portion of the pons contains structures involved in respiration, taste, and sleep.

The *midbrain*, the smallest part of the brain stem, lies rostral to the pons. Nuclei in the midbrain provide important linkages between components of the motor system, particularly the cerebellum, basal ganglia, and cerebral hemispheres. For example, the substantia nigra provides important input to a portion of the basal ganglia that regulates voluntary movements. The substantia nigra is the focus of intense interest as damage to its dopaminergic neurons is responsible for the pronounced motor disturbances that are characteristic of Parkinson disease (see Chapter 43). The midbrain also contains components of the auditory and visual systems. Finally, several regions of the midbrain give rise to pathways that are connected to the extraocular muscles that control eye movements.

The brain stem has five distinct functions. First, just as the spinal cord mediates sensation and motor control of the trunk and limbs, the brain stem mediates sensation and motor control of the head, neck, and face. The sensory input and motor output of the brain stem is carried by 12 cranial nerves that are functionally analogous to the 31 spinal nerves. Second, the brain stem is the site of entry for information from several specialized senses, such as hearing, balance, and taste. Third, specialized neurons in the brain stem mediate parasympathetic reflexes, such as decreases in cardiac output and blood pressure, increased peristalsis of the gut, and constriction of the pupils. Fourth, the brain stem contains ascending and descending pathways that carry sensory and motor information to other divisions of the central nervous system. Fifth, a relatively diffuse network of neurons distributed throughout the core of the brain stem, known as the reticular formation, receives a summary of much of the incoming sensory information and is important in regulating alertness and arousal.

The *cerebellum* lies over the pons and is divided into several lobes by distinct fissures. The cerebellum

is important for maintaining posture and coordinating head, eye, and arm movements, and is also involved in minute regulation of motor output and learning motor skills. Until recently, the cerebellum was considered a purely motor structure, but new anatomical information about its interconnections with the cerebral cortex and functional imaging studies have shown that it is also involved in language and other cognitive functions. The cerebellum contains far more neurons than any other single subdivision of the brain, including the cerebral hemispheres. Its internal circuitry, however, is well understood because relatively few types of neurons are involved. The cerebellum receives information about somatic sensation from the spinal cord, information about balance from the vestibular organs of the inner ear, and motor and sensory information from various areas of the cerebral cortex via the pontine nuclei.

The diencephalon contains two major subdivisions: the thalamus and hypothalamus. The thalamus is an essential link in the pathway of sensory information from the periphery (other than olfactory receptors in the nose) to sensory regions of the cerebral hemispheres. It once was thought to act only as a relay station for sensory information traveling to the neocortex, but now it is clear that it also determines which sensory information reaches the neocortex. The thalamus also interconnects the cerebellum and basal ganglia with regions of the cerebral cortex concerned with movement and cognition. Like the reticular formation, the diencephalon also has regions that are thought to influence levels of attention and consciousness.

The hypothalamus lies ventral to the thalamus and regulates homeostasis and several reproductive behaviors. For example, it plays an important role in somatic growth, eating, drinking, and maternal behavior by regulating the hormonal secretions of the pituitary gland. The hypothalamus also influences behavior through its extensive afferent and efferent connections with practically every region of the central nervous system. It is an essential component of the motivational systems of the brain, initiating and maintaining behaviors the organism finds aversive or rewarding. Finally, one group of neurons in the hypothalamus, the suprachiasmatic nucleus, regulates circadian rhythms, cyclical behaviors that are entrained to the daily light-dark cycle.

The *cerebral hemispheres* are the largest part of the human brain. They consist of the cerebral cortex, the underlying white matter, and three deep-lying structures: the basal ganglia, amygdala, and hippocampal formation. The cerebral hemispheres have perceptual, motor, and cognitive functions, including

memory and emotion. The two hemispheres are interconnected by the corpus callosum, which is visible on the medial surface of the hemispheres. The corpus callosum is the largest of the commissures (large bundles of axons that mainly link similar regions of the left and right sides of the brain). The amygdala is concerned with the expression of emotion, the hippocampus with memory formation, and the basal ganglia with the control of movement and aspects of motor learning.

While the spinal cord, brain stem, and diencephalon mediate many life-sustaining functions, it is the cerebral cortex—the thin outer layer of the cerebral hemispheres—that is responsible for much of the planning and execution of actions in everyday life. The cerebral cortex is divided into four major lobes—frontal, parietal, temporal, and occipital—named after the overlying cranial bones (Figure 15–4). Each lobe includes many distinct functional subregions. The temporal lobe, for example, has distinct regions with auditory, visual, or memory functions.

Two additional regions of the cerebral cortex are the cingulate cortex, which surrounds the dorsal surface of the corpus callosum and is involved in the regulation of emotion and cognition, and the insular cortex (insula), which is not visible on the surface owing to the overgrowth of the frontal, parietal, and temporal lobes (Figure 15–5) and is concerned with emotion and the regulation of homeostasis. The overhanging portion of the cerebral cortex that buries the insula within the lateral sulcus is called the operculum.

Although the cerebral cortex on both sides of the brain is generally similar, some areas of cortex on the two sides are functionally distinct. In right-handed people, for example, portions of the left cerebral cortex are specialized for language, whereas the right side of the brain is more related to visuospatial information processing.

In the mid-19th century Pierre Paul Broca first called attention to portions of the frontal, parietal, and temporal lobes that encircle the fluid-filled ventricles of the brain, forming a continuous region at the border of the cerebral cortex. He named this region the limbic lobe (Latin *limbus*, border). The limbic lobe is no longer considered one of the major subdivisions of the cerebral cortex. However, the cingulate gyrus, which surrounds the corpus callosum and occupies much of Broca's limbic lobe (Figure 15–4), is a separate division of the neocortex, much like the insular cortex.

Distinct functional components of the neural system are connected to each other via discrete pathways, that is, tracts of bundled axons from one discrete population of neurons that terminate in another discrete population. Some of these pathways are very large and can be seen with the unaided eye in the gross brain. The pyramidal tracts, for example, project conspicuously from the cerebral cortex to the spinal cord. Most pathways are not nearly as prominent but can be demonstrated with neuroanatomical tracing techniques (see Box 4–2).

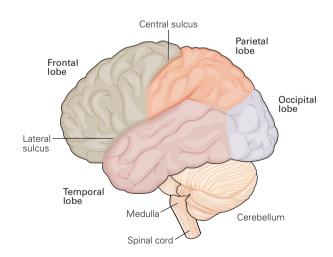

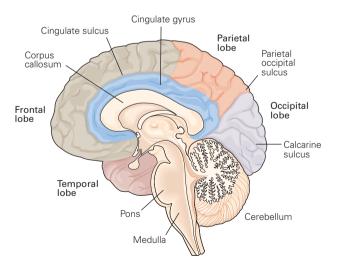

Figure 15–4 The major lobes and some prominent sulci of the human cerebral cortex. A lateral view of the left side of the brain is shown at left and a medial view of the right side

of the brain at right. (Reproduced, with permission, from Martin 2003.)

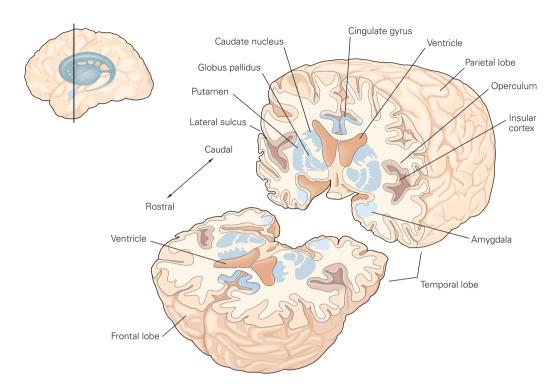

Figure 15–5 Structures in the middle of the cerebral hemispheres. These include the basal ganglia (caudate nucleus and globus pallidus) and insular cortex. Large cavities in the brain

called ventricles are filled with cerebrospinal fluid. (Adapted, with permission, from England and Wakely 1991.)

The Major Functional Systems Are Similarly Organized

The central nervous system consists of several functional systems that are relatively autonomous. There are, for example, discrete systems for each of the five special senses (touch, vision, hearing, taste, smell), for different classes of movement (eye movements, arm movements, hand movements), and for language. Each functional system comprises numerous interconnected anatomical sites throughout the brain.

These several functional systems of the brain must act together cooperatively. In sensory systems, for example, sensory neurons in the periphery project, directly or indirectly, to one or more regions in the spinal cord, brain stem, and thalamus. The thalamus projects to the primary sensory areas of cerebral cortex, which in turn project to other regions of cortex.

Information Is Transformed at Each Synaptic Relay

The output of each synaptic relay in a functional pathway is rarely the same as its input. For example, information may be amplified or attenuated depending on

the arousal level of the animal. A single neuron typically receives signals from thousands of presynaptic neurons, and the summation of all of these inputs determines the output of the neuron. The information encoded by each successive neuron in a functional pathway is typically more complex than the output of the preceding neuron.

Neurons at Each Synaptic Relay Are Organized into a Neural Map of the Body

One of the most striking features of the organization of most sensory systems is that the inputs from peripheral receptive surfaces—the retina of the eye, the cochlea of the inner ear, and the surface of the skin—are arranged topographically throughout successive stages of processing. Neighboring groups of cells in the retina, for example, project to neighboring groups of cells in nuclei of the thalamus, which, in turn, project to neighboring regions of the visual cortex. In this way the neurons at each successive relay of a sensory pathway form an orderly neural map of information from the receptive surface.

These neural maps reflect not only the spatial arrangement of receptors but also the variation in receptor density throughout the receptive surface. The density of innervation in an area of skin, for example, determines the degree of sensitivity of that area to tactile stimuli. The central region of the retina, the fovea, has the highest density of photoreceptors of any part of the retina and thus the greatest visual acuity. Correspondingly, the area of visual cortex devoted to information from the fovea is greater than the areas representing the peripheral portions of the retina, where the density of receptors (and visual acuity) is lower.

Similarly, in successive stages of cortical motor pathways the neurons that regulate particular body parts are clustered together to form a motor map; the most well-defined motor map is in the primary motor cortex. Motor maps, like sensory maps, do not represent every part of the body equally. The extent of the representation of a body part in a motor map reflects the density of innervation of that part, and thus the fineness of control required for movements in that part.

Each Functional System Is Hierarchically Organized

Information processing in sensory and motor systems is organized hierarchically. Within a system some areas of the cerebral cortex are designated as primary, secondary, or tertiary areas, depending on their functional sequence within the pathway. For example, the primary motor cortex mediates voluntary movements of the limbs and trunk; it is called primary because it contains neurons that directly activate somatic motor neurons in the spinal cord. The primary sensory areas receive most of their information from the thalamus, which receives signals from the peripheral receptors with only a few intervening synaptic relays. Whereas the primary sensory areas of cortex are the initial site of cortical processing of sensory information, the primary motor cortex is the *final* site in the cortex for processing motor commands.

The primary visual cortex is located caudally in the occipital lobe and is predominantly associated with the prominent calcarine sulcus (see Figure 15–4). The primary auditory cortex is located in the temporal lobe, where it is associated with a series of gyri (Heschl's gyri) on the lateral sulcus. The primary somatosensory cortex is located caudal to the central sulcus on the postcentral gyrus, in the parietal lobe.

Each primary sensory area conveys information to an adjacent, higher-order area, a unimodal association area where individual neurons selectively encode specific features of sensory stimuli and together represent complex information. At very advanced stages of the visual system, individual neurons are responsive to highly integrated information, such as the shape of a face.

Each higher-order sensory area sends its outputs to one or another of three major multimodal association areas that integrate information from two or more sensory modalities and coordinate this information with plans for action (see Chapter 18). Complex sensory information is also sent to higher-order motor areas, located rostral to the primary motor cortex in the frontal lobe, where programs for movement, or potential movements, are calculated and conveyed to the primary motor cortex for implementation. Some of the motor areas in the frontal lobe also send commands directly to the spinal cord. Cells in the primary motor cortex influence neurons in the ventral horn of the spinal cord responsible for muscle movements, and thus the primary motor cortex is intimately associated with the motor systems of the spinal cord.

Functional Systems on One Side of the Brain Control the Other Side of the Body

Most pathways in the central nervous system are bilaterally symmetrical and cross over to the opposite (contralateral) side of the brain or spinal cord. As a result, sensory and motor activities on one side of the body are mediated by the cerebral hemisphere on the opposite side. Thus, movement on the left side of the body is largely controlled by neurons in the right motor cortex.

The pathways of different systems cross at different anatomical levels within the brain. For example, the ascending pathways for pain cross in the spinal cord almost immediately upon entering the central nervous system. The sensory pathway for fine touch, however, ascends on the same side of the spinal cord that it enters. At the medulla, where it makes its first synapse, second-order fibers cross over to the thalamus on the contralateral side. Crossings of this kind within the brain stem and spinal cord are called *decussations*.

The Cerebral Cortex Is Concerned with Cognition

Phylogenetically, humans have the most elaborate cerebral cortex. The four lobes of the cerebral cortex have a highly convoluted shape, formed by indentations or grooves (*sulci*) that separate elevated regions (*gyri*), which occupy a relatively consistent position across individuals. One of the most prominent indentations, the lateral sulcus or sylvian fissure, separates the temporal lobe from the frontal and parietal lobes (see Figure 15–4). Another prominent indentation, the central sulcus, runs

medially and laterally on the dorsal surface of the hemisphere and separates the frontal and parietal lobes.

It is likely that this convoluted shape arose during evolution as a strategy for packing ever-increasing numbers of neurons into the limited space of the skull, as the thickness of the cortex does not vary substantially in different species (always approximately 2 to 4 mm thick), although the surface area is dramatically larger in higher primates, particularly in humans. By allowing for a greater number of cortical neurons, an increase in the surface area of the cortex provides a greater capacity for processing information.

Neurons in the Cerebral Cortex Are Organized in Layers and Columns

The neocortex—the region of cerebral cortex nearest the surface of the brain—is organized into layers

and columns, an arrangement that increases the computational efficiency of the cerebral cortex. As we shall see below, the subcortical regions have a nuclear organization.

The neocortex receives inputs from the thalamus, other cortical regions on both sides of the brain, and other structures. Its output is directed to other regions of the neocortex, basal ganglia, thalamus, pontine nuclei, and the spinal cord. These complex input—output relationships are efficiently organized in the orderly layering of cortical neurons; each layer contains different inputs and outputs. Most of the neocortex contains six layers, numbered from the outer surface (pia mater) of the cortex to the white matter (Figure 15–6).

Layer I, the *molecular layer*, is occupied by the dendrites of cells located in deeper layers and axons that travel through this layer to make connections in other areas of the cortex.

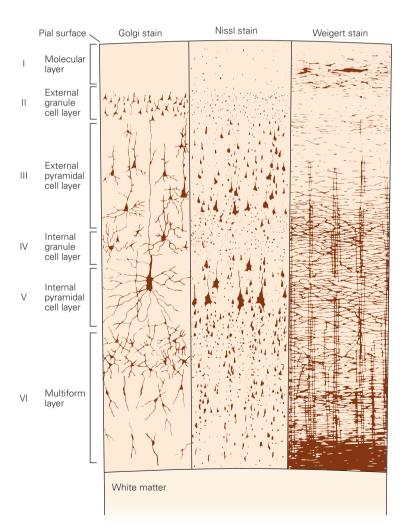

Figure 15–6 The neurons of the neocortex are arranged in distinctive layers. The appearance of the neocortex depends on what is used to stain it. The Golgi stain reveals a subset of neuronal cell bodies, axons, and dendritic trees. The Nissl method shows cell bodies and proximal dendrites. A Weigert stain reveals the pattern of myelinated fibers. (Reproduced, with permission, from Heimer 1994.)

Layers II and III contain mainly small pyramidal shaped cells. Layer II, the *external granular cell layer*, is one of two layers that contain small spherical neurons. Layer III is called the *external pyramidal cell layer* (an internal pyramidal cell layer lies at a deeper level). The neurons located deeper in layer III are typically larger than those located more superficially. The axons of pyramidal neurons in layers II and III project locally to other neurons within the same cortical area as well as to other cortical areas, thereby mediating intracortical communication (Figure 15–7).

Layer IV contains a large number of small spherical neurons and thus is called the *internal granular cell layer*. It is the main recipient of sensory input from the thalamus and is most prominent in primary sensory areas. For example, the region of the occipital cortex that functions as the primary visual cortex has an extremely prominent layer IV (Figure 15–8). Layer IV in this region is so heavily populated by neurons and so complex that it is typically divided into three sublayers. Areas with a prominent layer IV are called *granular cortex*. In contrast the precentral gyrus, the site of the primary motor cortex, has essentially no layer IV (Figure 15–8) and is thus part of the so-called *agranular*

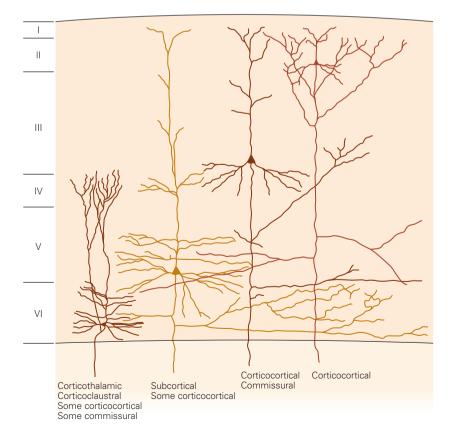

frontal cortex. These two cortical areas are among the easiest to identify in histological sections.

Layer V, the *internal pyramidal cell layer*, contains mainly pyramidally shaped cells that are typically larger than those in layer III. Pyramidal neurons in this layer give rise to the major output pathways of the cortex, projecting to other cortical areas and to subcortical structures (Figure 15–7).

The neurons in layer VI are fairly heterogeneous and thus this layer is called the *polymorphic* or *multi-form layer*. It blends into the white matter that forms the deep limit of the cortex and carries axons to and from areas of cortex.

Although each layer of the neocortex is defined primarily by the presence, absence, and packing density of distinctive cell types, each layer also contains the dendrites of specific cortical neurons. Layers I through III contain the apical dendrites of neurons that have their cell bodies in layers V and VI, as well as in layers II and III, whereas layers V and VI contain the basal dendrites of neurons with cell bodies in layers III and IV, as well as in layers V and VI (Figure 15–7). The inputs to a cortical neuron thus depend on the location of its dendrites and cell body.

Figure 15–7 Neurons in different layers of neocortex project to different parts of the brain. Projections to other parts of the neocortex, the so-called corticocortical or associational connections, arise primarily from neurons in layers II and III. Projections to subcortical regions arise mainly from layers V and VI. (Reproduced, with permission, from Jones 1986.)

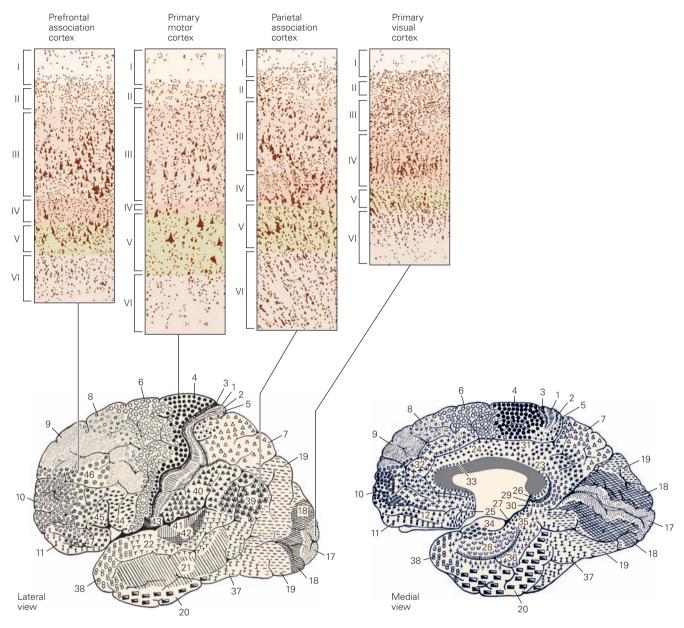

Figure 15–8 The extent of each cell layer of the neocortex varies throughout the cortex. Sensory areas of cortex, such as the primary visual cortex, tend to have a very prominent internal granular cell layer (layer IV), the site of sensory input. Motor areas of cortex, such as the primary motor cortex, have a very meager layer IV but prominent output layers, such as

layer V. These differences led Korbinian Brodmann and others working at the turn of the 20th century to divide the cortex into various cytoarchitectonic regions. Brodmann's 1909 subdivision shown here is a classic analysis but was based on a single human brain. (Reproduced, with permission, from Martin 2003.)

The thickness of individual layers and the details of their functional organization vary throughout the cortex. An early student of the cerebral cortex, Korbinian Brodmann, used the relative prominence of the layers above and below layer IV, cell size, and packing characteristics to distinguish different areas of

the neocortex. Based on such cytoarchitectonic differences, Brodmann in 1909 divided the cerebral cortex into 47 regions (Figure 15–8).

Although Brodmann's demarcation coincides, in part, with recent information on localized functions in the neocortex, the cytoarchitectonic method alone does

not capture the subtlety or variety of function of all the distinct regions of the cortex. For example, Brodmann identified five regions (areas 17–21) as being concerned with visual function in the monkey. In contrast, modern connectional neuroanatomy and electrophysiology have identified more than 35 functionally distinct cortical regions within the five regions studied by Brodmann.

Within the neocortex information passes from one synaptic relay to another using feedforward and feedback connections. In the visual system, for example, feedforward projections from the primary visual cortex to secondary and tertiary visual areas originate mainly in layer III and terminate mainly in layer IV of the target cortical area. In contrast, feedback projections to earlier stages of processing originate from cells in layers V and VI and terminate in layers I, II, and VI (Figure 15–9).

Neurons in the neocortex are often organized into columns that run from the white matter to the pial surface, thus traversing the layers. (This columnar organization is not particularly evident in standard histological preparations.) Each column is a fraction of a millimeter in diameter. Neurons within a column tend to have very similar response properties, presumably because they form a local processing network. Columns are thought to be the fundamental computational modules of the neocortex (see Chapter 22).

The Cerebral Cortex Has a Large Variety of Neurons

The neurons of the cortex have a variety of shapes and sizes. Raphael Lorente de Nó, a student of Santiago Ramón y Cajal, used the Golgi stain to identify more than 40 different types of cortical neurons based only on the distribution of their dendrites and axons. The neurons of the cortex, as elsewhere, can be broadly defined as either principal (projection) neurons or local

interneurons. Projection neurons typically have pyramidshaped cell bodies (Figure 15–10). They are located mainly in layers III, V, and VI and use the amino acid glutamate as their primary transmitter at excitatory synapses. The axons of principal neurons convey information to the next synaptic relay in the system.

Local interneurons have axons that remain within the same area where their cell body is located and use the neurotransmitter γ -aminobutyric acid (GABA) at inhibitory synapses. These interneurons constitute 20% to 25% of the neurons in the neocortex and are located in all layers. Interneurons may receive inputs from the same sources as the principal cells.

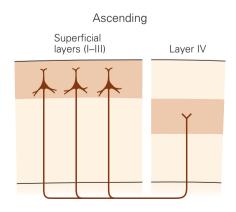

Several types of GABAergic interneurons have been distinguished based on their pattern of connections and the cotransmitters they use with GABA (Figure 15–11). Basket cells form axosomatic synapses, that is, their axons terminate on the cell bodies of target neurons. Other interneurons form axo-axonic synapses, that is, their axons terminate exclusively on the axons of target neurons. The multiple arrays of synaptic terminals formed by these cells resemble a chandelier and thus these cells are typically called *chandelier cells*.

The neocortex also has a population of excitatory interneurons, located primarily in layer IV. These cells have star-shaped dendritic trees and use glutamate as a transmitter. These excitatory interneurons are the primary recipients of sensory information from the thalamus.

Subcortical Regions of the Brain Are Functionally Organized into Nuclei

Three major structures lie deep within the cerebral hemispheres: the basal ganglia, the hippocampal formation, and the amygdala. These three subcortical structures act to regulate cortical activity.

Figure 15–9 Ascending and descending cortical pathways are distinguished by the organization of their pre- and postsynaptic connections within the cortical layers. Ascending or feedforward pathways generally originate in superficial layers of the cortex and invariably terminate in layer IV. Descending or feedback pathways generally originate from deep layers and terminate in layers I and VI. (Adapted, with permission, from Felleman and Van Essen 1991.)

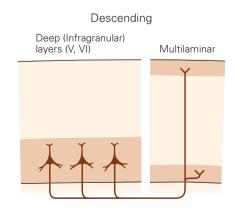

Figure 15–10 A projection neuron and interneuron in the somatic sensory cortex of a monkey. These photomicrographs were made at different depths of focus through the same Golgi-stained preparation. A Golgi type I pyramidal cell (P) in layer V is seen better on the left, whereas a Golgi type II interneuron (I) in layers II—III is seen better on the right. (Reproduced, with permission, from Jones 1986.)

Neurons in the basal ganglia regulate movement and contribute to certain cognitive functions such as the learning of motor skills. The basal ganglia receive input from all parts of the cerebral cortex but send their output largely through the thalamus to the frontal lobe. The basal ganglia have five major functional subcomponents: the caudate nucleus, putamen, globus pallidus, subthalamic nucleus, and substantia nigra (Figure 15–12).

The hippocampal formation includes the hippocampus, dentate gyrus, and subiculum. The hippocampus and associated cortical regions form the floor of the temporal horn of the lateral ventricle (Figure 15–12). Together these structures are responsible for the formation of long-term memories about our daily experiences, so-called episodic memories, but are not the permanent storage site of these memories (see Chapter 65). Damage to the hippocampus interferes with people's ability to form new memories but does not significantly impair the ability to retrieve old memories.

The amygdala, which lies just rostral to the hippocampus, is involved in analyzing the emotional or motivational significance of sensory stimuli. It receives input directly from the major sensory systems. Neurons in the amygdala project to the neocortex, basal ganglia, hippocampus, and a variety of subcortical structures including the hypothalamus. Projections to the brain stem can modulate somatic and visceral components of emotion. For example, the amygdala mediates the unconscious responses to danger—changes in heart rate, respiration, and pupillary dilation—as well as the conscious emotional perception of fear.

Thin histological sections through the diencephalon and brain stem reveal the structure of several nuclei. Most nuclei are not homogeneous populations of cells but instead comprise a variety of cells of different sizes and shapes organized into subnuclei, divisions, or layers. A nucleus that appears homogeneous when viewed with the nonspecific Nissl stain (Figure 15–13) may

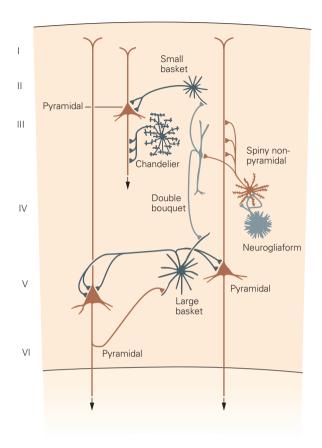

Figure 15–11 The cerebral cortex has several types of GABAergic interneurons. Known types of GABAergic neurons (dark gray) and putative types (light gray) have different connections with projection neurons in the neocortex. The known GABAergic cells include chandelier cells, which terminate exclusively on the axons of pyramidal neurons, and the large and small basket cells, whose axons terminate mainly on the cell bodies of pyramidal neurons. Double bouquet and neurogliaform cells may also be GABAergic. The neurogliaform cells form axosomatic synapses on spiny pyramidal neurons. (Adapted, with permission, from Houser et al. 1986.)

actually prove to be organizationally complex when viewed with other stains that highlight the structure of dendrites (such as the Golgi technique) or the chemical composition of the neurons (such as histochemistry or immunohistochemistry). Neurons in the lateral geniculate nucleus of the thalamus, for example, are grouped into alternating bands of neurons with different functions (Figure 15–14).

The characterization of a nucleus in the brain thus depends on the method by which the neurons are visualized. Indeed, modern neuroanatomy, based on the molecular characterization of different nerve cell types, has contributed greatly to the definition of brain regions. One particularly telling example occurred in the 1970s when Bengt Falck and Nils Hillarp developed a histofluorescence technique for staining monoamine neurotransmitters (see Box 13-2). This technique allowed researchers to deconstruct the reticular formation, a region of the brain stem so named because of its diffuse and seemingly chaotic appearance. We now understand that this region is finely organized into groups of cells characterized by transmitter phenotype (serotonergic, noradrenergic, or dopaminergic). Many other powerful techniques for defining the chemical or genetic composition of neuronal types have emerged in the last few decades. For example, in situ hybridization allows neurons to be visualized based on the genes they express (see Box 13-2). This has led to the tongue-in-cheek saying that "the gains in brain lie mainly in the stain."

Modulatory Systems in the Brain Influence Motivation, Emotion, and Memory

Some areas of the brain are neither purely sensory nor purely motor but instead modify specific sensory or motor functions. Modulatory systems are often involved in behaviors that respond to a primary need such as hunger, thirst, or sleep. For example, sensory and modulatory systems in the hypothalamus determine blood glucose levels. When blood sugar drops below a certain critical level, we feel hunger. To satisfy hunger, modulatory systems in the brain focus vision, hearing, and smell on stimuli that are relevant to feeding.

Distinct modulatory systems within the brain stem modulate attention and arousal. Small groups of adrenergic and serotonergic modulatory neurons in the brain stem set the general arousal level of an animal through their connections with forebrain structures. As we will discuss further in Chapter 46, a group of cholinergic modulatory neurons, the basal nucleus of Meynert, is also involved in arousal or attention. It is located beneath the basal ganglia in the basal forebrain portion of the telencephalon. The axons of the neurons in this nucleus project to essentially all portions of the neocortex.

If a predator finds potential prey, a variety of cortical and subcortical systems determine whether the prey is edible. Once food is recognized, other cortical and subcortical systems initiate a comprehensive voluntary motor program to bring the animal into contact with the prey, capture it and place it in the mouth, and chew and swallow.

Finally, the physiological satisfaction the animal experiences in eating reinforces the behaviors that

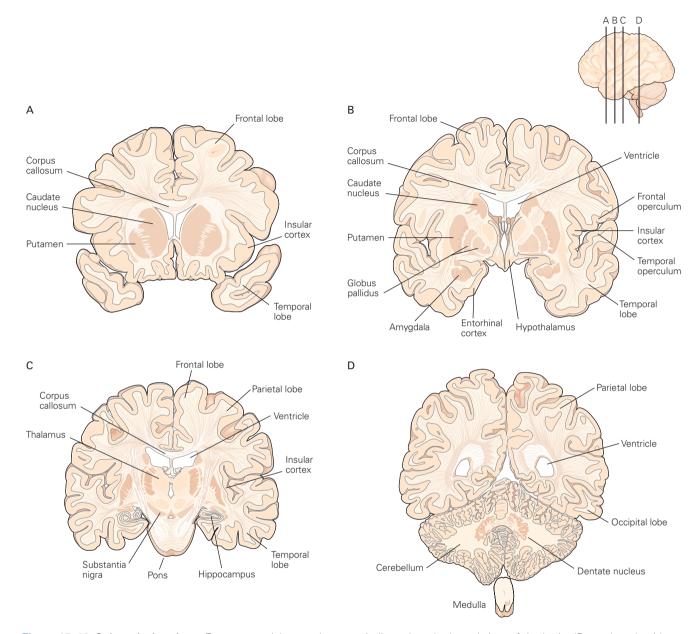

Figure 15–12 Subcortical regions. Four sequential coronal sections (A–D) were made in the rostral-caudal sequence

indicated on the lateral view of the brain. (Reproduced, with permission, from Nieuwenhuys, Voogd, and van Huijzen 1988.)

led to the successful predation. A group of dopaminergic neurons in the midbrain are important for monitoring reinforcements and rewards. The power of the dopaminergic modulatory systems has been demonstrated by experiments in which electrodes were implanted into the reward regions of rats and the animals were freely allowed to press a lever to electrically stimulate their brains. They preferred this self-stimulation to obtaining food or water,

engaging in sexual behavior, or any other naturally rewarding activity.

How the brain's modulatory systems concerned with reward, attention, and motivation interact with the sensory and motor systems is one of the most interesting questions in neuroscience, one that is also fundamental to our understanding of learning and memory storage. We take up this discussion in detail in Chapter 46

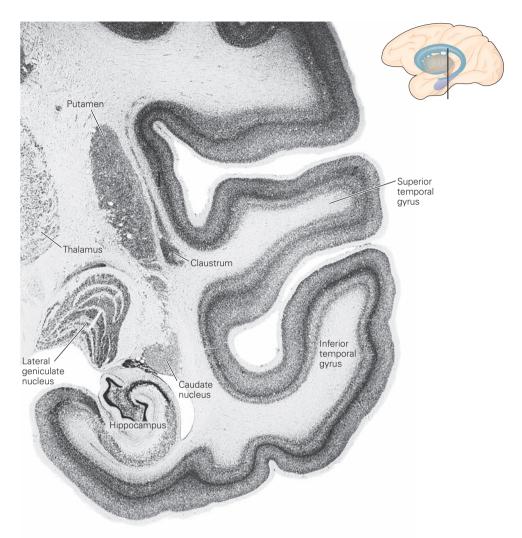

Figure 15–13 Several nuclei and cortical areas are visible in the right hemisphere of a Macaque monkey brain. Neuronal and glial cell bodies show up as the grainy dark portions of this low-magnification photograph of a Nissl-stained coronal section. The layering of the neurons of the lateral geniculate nucleus of the thalamus can be seen (see also Figure 15–14).

Layering also occurs in the hippocampus and the neocortex of the temporal lobe. Other nuclei are more homogeneous, such as the caudate nucleus, putamen, and claustrum. The white regions between the clusters of neurons constitute the white matter where axons run from one brain region to one or more other regions.

The Peripheral Nervous System Is Anatomically Distinct from the Central Nervous System

The peripheral nervous system supplies the central nervous system with a continuous stream of information about both the external environment and the internal environment of the body. It has somatic and autonomic divisions (Figure 15–15).

The *somatic division* includes the sensory neurons that receive information from the skin, muscles, and

joints. The cell bodies of these sensory neurons lie in the dorsal root ganglia and cranial ganglia. Receptors associated with these cells provide information about muscle and limb position and about touch and pressure at the body surface. In Part V (Perception) we shall see how remarkably specialized these receptors are in transducing one or another type of physical energy (such as deep pressure or heat) into the electrical signals used by the nervous system. In Part VI (Movement) we shall see that sensory receptors in the muscles and joints are crucial to shaping coherent movement of the body.

The *autonomic division* of the peripheral nervous system mediates visceral sensation as well as motor control of the viscera, vascular system, and exocrine glands. It consists of the sympathetic, parasympathetic, and enteric systems. The sympathetic system participates in the body's response to stress, whereas the parasympathetic system acts to conserve body resources and restore homeostasis. The enteric nervous system, with neuronal cell bodies located in or adjacent to the viscera, controls the function of smooth muscle of the gut. The functional organization of the autonomic nervous system is described in Chapter 47 and its role in emotion and motivation in Chapters 48 and 49.

An Overall View

The nervous system receives sensory information from the environment, evaluates the significance of the information, and generates appropriate behavioral responses. Accomplishing these tasks requires an anatomical plan of considerable complexity. The human nervous system is comprised of approximately 100 billion neurons, each of which receives and gives rise to thousands of connections. Some of these connections are formed nearly a meter from the cell body of the neuron.

Despite this complexity, the structure of the nervous system is similar in individuals of a species.

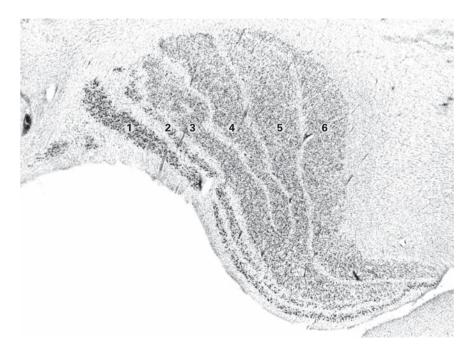

Knowledge of neuronal structure and the pathways of information flow in the brain is important not only for understanding the normal function of the brain but also for identifying specific regions that are disturbed during neurological illness.

The nervous system has two anatomically distinct components. The central nervous system consists of the brain and spinal cord, while the peripheral nervous system is composed of specialized clusters of neurons (ganglia) and peripheral nerves. The peripheral nervous system relays information to the central nervous system and executes motor commands generated in the brain and spinal cord. Even the simplest behavior involves the integrated activity of several sensory, motor, and functional pathways are precisely arranged synaptic relays made up of clusters or layers of neurons called nuclei. Each functional pathway normally has the same anatomical arrangement in every individual.

Although neuroanatomy may seem to provide only a static picture of the nervous system, it can provide profound insight into how the nervous system functions, in the same way that the detailed structure of proteins reveals important principles of protein function. Understanding brain function therefore depends on an understanding of both structure and function, and crucially, of the relation between the two.

As we shall see in later chapters, modern neuroimaging has revolutionized the study of the cognitive

Figure 15–14 The lateral geniculate nucleus is an example of a complex nucleus. The nucleus is shown in a Nissl-stained coronal section of the right hemisphere of a human brain. Axons from different types of neurons in the retina terminate in different layers (1–6) of the nucleus. In addition, each layer receives input from only one eye. Each layer contains both projection neurons and interneurons. (The nucleus is described in detail in Chapter 26 in the discussion of visual perception.)

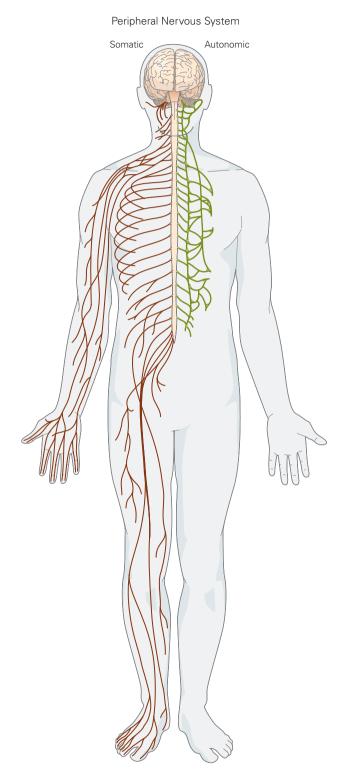

Figure 15–15 The peripheral nervous system has somatic and autonomic divisions. The somatic division carries information from the skin to the brain and from the brain to muscles. The autonomic division regulates involuntary functions, including activity of the heart and smooth muscles in the gut and glands.

operations of the brain. In particular, positron emission tomography (PET) and magnetic resonance imaging (MRI) have made the functional organization of the intact human brain visible during behavioral experiments. These techniques, in addition to being important tools for diagnosing diseases of the central nervous system, have given us a much clearer idea of the functional specialization of the nervous system. Importantly, they have placed neurology and psychiatry on a firmer empirical footing.

The Thalamus Is an Essential Link Between Sensory Receptors and the Cerebral Cortex for All Modalities Except Olfaction

Sensory Information Processing Culminates in the Cerebral Cortex

Voluntary Movement Is Mediated by Direct Connections Between the Cortex and Spinal Cord

An Overall View

The Human brain identifies objects and carries out actions in ways no current computer can even begin to approach. Merely to see—to look onto the world and recognize a face or facial expression—entails amazing computational achievements. Indeed, all our perceptual abilities—seeing, hearing, smelling, tasting, and touching—are analytical triumphs. Similarly, all of our voluntary actions are triumphs of engineering. The brain accomplishes these computational feats because its information processing units—its nerve cells—are wired together in very precise ways.

In this chapter we outline the neuroanatomical organization of perception and action. We focus on touch because the somatosensory system is particularly well understood and because touch clearly illustrates the interaction of sensory and motor systems—how information from the body surface ascends through the sensory relays of the nervous system to the cerebral cortex and is transformed into motor commands that descend to the spinal cord to produce movements.

We now have a fairly complete understanding of how the physical energy of a tactile stimulus is transduced by mechanoreceptors in the skin into electrical activity, and how this activity at different relays in the brain correlates with specific aspects of the experience of touch. Moreover, because the pathways from one relay to the next are well delineated, we can see how sensory information is coded at each relay.

Trying to comprehend the functional organization of the brain might at first seem daunting. But as we saw in the last chapter, the organization of the brain is simplified by three anatomical considerations. First, there are relatively few types of neurons. Each of the many thousands of spinal motor neurons or millions of neocortical pyramidal cells has a similar structure and serves a similar function. Second, neurons in the brain and spinal cord are clustered in discrete functional groups called nuclei, which are connected to form functional systems. Third, specific regions of the cerebral cortex are specialized for sensory, motor, or, as we shall learn in detail in Chapters 17 and 18, associational functions.

Sensory Information Processing Is Illustrated in the Somatosensory System

Complex behaviors, such as using touch alone to differentiate a ball from a book, require the integrated action of several nuclei and cortical regions. Information is processed in the brain in a hierarchical fashion. Thus information about a stimulus is conveyed through a succession of subcortical and then cortical regions and at each level of processing the information becomes increasingly complex. In addition, different types of information, even within a single sensory modality, are processed in several anatomically discrete pathways.

In the somatosensory system a light touch and a painful pin prick to the same area of skin are mediated by different pathways in the brain.

Somatosensory Information from the Trunk and Limbs Is Conveyed to the Spinal Cord

Sensory information from the trunk and limbs enters the spinal cord, which has a core H-shape region of gray matter surrounded by white matter. The gray matter on each side of the cord is divided into dorsal (or posterior) and ventral (or anterior) horns (Figure 16–1). The dorsal horn contains groups of sensory neurons

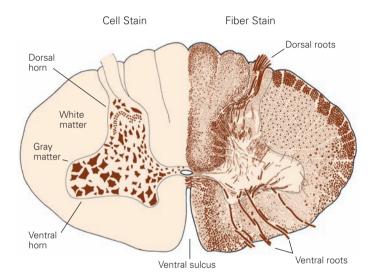

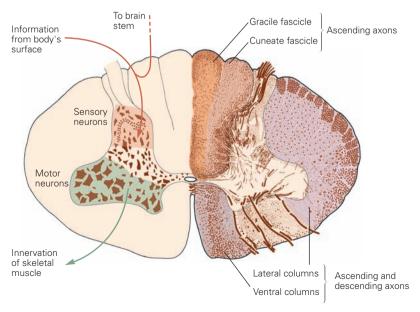

Figure 16–1 The major anatomical features of the spinal cord. Top: The left side depicts a cell stain of the gray matter and the right side a fiber-stained section. Bottom: The ventral horn (green) contains large motor neurons, whereas the dorsal horn (orange) contains smaller neurons. Fibers of the gracile fascicle carry somatosensory information from the lower limbs, whereas fibers of the cuneate fascicle carry somatosensory information from the upper body. Fiber bundles of the lateral and ventral columns include both ascending and descending fiber bundles.

(sensory nuclei) whose axons receive stimulus information from the body's surface. The ventral horn contains groups of motor neurons (motor nuclei) whose axons exit the spinal cord and innervate skeletal muscles.

Unlike the sensory nuclei, the motor nuclei form columns that run the length of the spinal cord. Interneurons of various types in the gray matter inhibit the output of the spinal cord neurons. These inhibitory interneurons thus modulate both sensory information flowing toward the brain and motor commands descending from the brain to the spinal motor neurons. Motor neurons can also adjust the output of other motor neurons via the interneurons.

The white matter surrounding the gray matter contains bundles of ascending and descending axons that are divided into dorsal, lateral, and ventral columns. The dorsal columns, which lie between the two dorsal horns of the gray matter, contain only ascending axons that carry somatic sensory information to the brain stem (Figure 16-1). The lateral columns include both ascending axons and axons descending from the brain stem and neocortex that innervate spinal interneurons and motor neurons. The ventral columns also include ascending and descending axons. The ascending somatic sensory axons in the lateral and ventral columns constitute parallel pathways that convey information about pain and thermal sensation to higher levels of the central nervous system. The descending axons control axial muscles and posture.

The spinal cord is divided into four major regions: cervical, thoracic, lumbar, and sacral (Figure 16–2). These regions are related to the embryological somites from which muscles, bones, and other components of the body develop (see Chapters 52 and 53). Axons projecting from the spinal cord to body structures that develop at the same segmental level join together in the intervertebral foramen with axons entering the spinal cord to form spinal nerves. Spinal nerves at the cervical level are involved with sensory perception and motor function of the back of the head, neck, and arms; nerves at the thoracic level innervate the upper trunk; whereas lumbar and sacral spinal nerves innervate the lower trunk, back, and legs.

Each of the four regions of the spinal cord contains several segments; there are 8 cervical segments, 12 thoracic segments, 5 lumbar segments, and 5 sacral segments. Although the actual substance of the mature spinal cord does not look segmented, the segments of the four spinal regions are nonetheless defined by the number and location of the dorsal and ventral roots that enter or exit the cord. The spinal cord varies in size and shape along its rostrocaudal axis because of two organizational features.

First, relatively few sensory axons enter the cord at the sacral level. At higher levels (lumbar, thoracic, and cervical) the number of sensory axons entering the cord increases progressively. Conversely, most descending axons from the brain terminate at cervical levels, with progressively fewer descending to lower levels of the spinal cord. Thus the number of fibers in the white matter is highest at cervical levels (where there are the highest numbers of both ascending and descending fibers) and lowest at sacral levels. As a result, sacral levels of the spinal cord have much less white matter than gray matter, whereas the cervical cord has more white matter than gray matter (Figure 16–2).

The second organizational feature is variation in the size of the ventral and dorsal horns. The ventral horn is larger at the levels where the motor nerves that innervate the arms and legs exit the spinal cord. The number of ventral motor neurons dedicated to a body region roughly parallels the dexterity of movements of that region. Thus a larger number of motor neurons is needed to innervate the greater number of muscles and to regulate the greater complexity of movement in the limbs as compared with the trunk. Likewise, the dorsal horn is larger where sensory nerves from the limbs enter the cord. Limbs have a greater density of sensory receptors to mediate finer tactile discrimination and thus send more fibers to the cord. These regions of the cord are known as the lumbosacral and cervical enlargements.

The Primary Sensory Neurons of the Trunk and Limbs Are Clustered in the Dorsal Root Ganglia

The sensory neurons that convey information from the skin, muscles, and joints of the limbs and trunk to the spinal cord are clustered together in dorsal root ganglia within the vertebral column immediately adjacent to the spinal cord (Figure 16–3). These neurons are pseudo-unipolar in shape; they have a bifurcated axon with central and peripheral branches. The peripheral branch terminates in skin, muscle, or other tissue as a free nerve ending or in association with specialized receptors.

The central process enters the spinal cord. On entry the axon forms branches that either terminate within the spinal gray matter or ascend to nuclei located near the junction of the spinal cord with the medulla (Figure 16–3). These local and ascending branches provide two functional pathways for somatosensory information entering the spinal cord from dorsal root ganglion cells. The local branches can activate local reflex circuits while the ascending branches carry information into the brain, where this information becomes the raw material for the perception of touch, position sense, or pain.

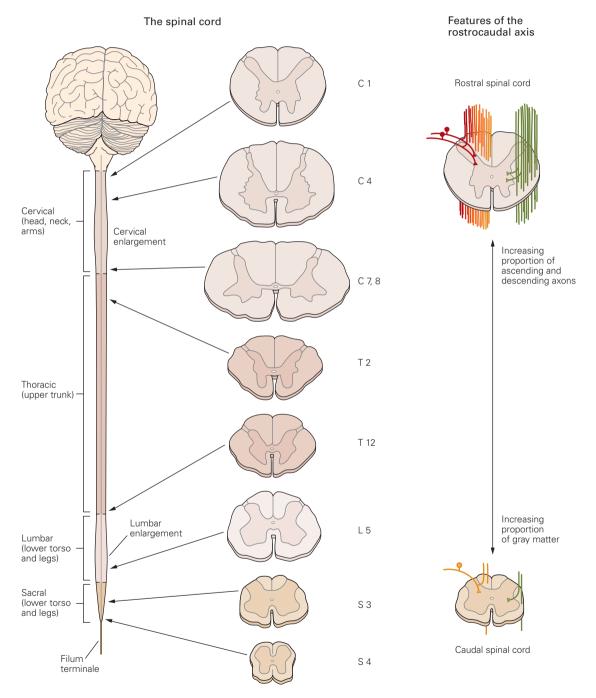

Figure 16–2 The internal and external appearances of the spinal cord vary at different levels. The proportion of gray matter (the H-shaped area within the spinal cord) to white matter is greater at sacral levels than at cervical levels. At sacral levels very few incoming sensory fibers have joined the spinal cord,

whereas most of the motor fibers have already terminated at higher levels of the spinal cord. The cross-sectional enlargements at the lumbar and cervical levels are regions where the large number of fibers innervating the limbs enter or leave the spinal cord.

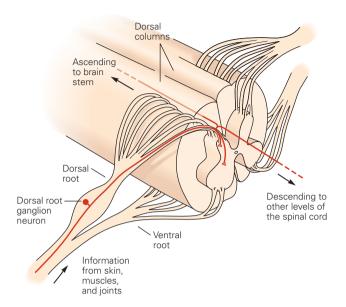

Figure 16–3 Dorsal root ganglia and spinal nerve roots. The cell bodies of neurons that bring sensory information from the skin, muscles, and joints lie in the dorsal root ganglia, clusters of cells that lie adjacent to the spinal cord. The axons of these neurons are bifurcated into peripheral and central branches. The central branch enters the dorsal portion of the spinal cord.

The Central Axons of Dorsal Root Ganglion Neurons Are Arranged to Produce a Map of the Body Surface

The central axons of the dorsal root ganglion cells form a neural map of the body surface when they terminate in the spinal cord. This orderly somatotopic distribution of inputs from different portions of the body surface is maintained throughout the entire ascending somatosensory pathway.

Axons that enter the cord in the sacral region ascend in the dorsal column near the midline, whereas those that enter at successively higher levels ascend at progressively more lateral positions within the dorsal columns. Thus, in the cervical cord, where axons from all portions of the body have already entered, sensory fibers from the lower body are located medially in the dorsal column, while fibers from the trunk, the arm and shoulder, and finally the neck occupy progressively more lateral areas. At cervical levels of the cord the axons forming the dorsal columns are divided into two bundles: a medially situated gracile fascicle and a more laterally situated cuneate fascicle (Figure 16–4).

Each Somatic Submodality Is Processed in a Distinct Subsystem from the Periphery to the Brain

The submodalities of somatic sensation—touch, pain, and position sense—are processed in the brain through different pathways that end in different brain regions. To illustrate the specificity of these parallel pathways, we will follow the path of information for the submodality of touch.

The primary afferent fibers that carry information about touch enter the ipsilateral dorsal column and, without crossing to the contralateral column, ascend to the medulla. Fibers from the lower body run in the gracile fascicle and terminate in the gracile nucleus, whereas fibers from the upper body run in the cuneate fascicle and terminate in the cuneate nucleus. Neurons in the gracile and cuneate nuclei give rise to axons that cross to the other side of the brain and ascend to the thalamus in a long fiber bundle called the medial lemniscus (Figure 16–4).

As in the dorsal columns of the spinal cord, the fibers of the medial lemniscus are arranged somatotopically. Because the sensory fibers cross the midline to the other side of the brain, the right side of the brain receives sensory information from the left side of the body, and vice versa. The fibers of the medial lemniscus end in a specific subdivision of the thalamus called the ventral posterior nucleus (Figure 16–4). There the fibers maintain their somatotopic organization such that those carrying information from the lower body end laterally and those carrying information from the upper body and face end medially.

The Thalamus Is an Essential Link Between Sensory Receptors and the Cerebral Cortex for All Modalities Except Olfaction

The thalamus is an egg-shaped structure that constitutes the dorsal portion of the diencephalon. It conveys sensory input to the primary sensory areas of the cerebral cortex but is more than simply a relay. It acts as a gatekeeper for information to the cerebral cortex, preventing or enhancing the passage of specific information depending on the behavioral state of the animal.

The thalamus is a good example of a brain region made up of several well-defined nuclei. As many as 50 thalamic nuclei have been identified. Some nuclei receive information specific to a sensory modality and project to a specific area of the neocortex. Cells in the ventral posterior lateral nucleus (where the medial lemniscus terminates) process somatosensory information,

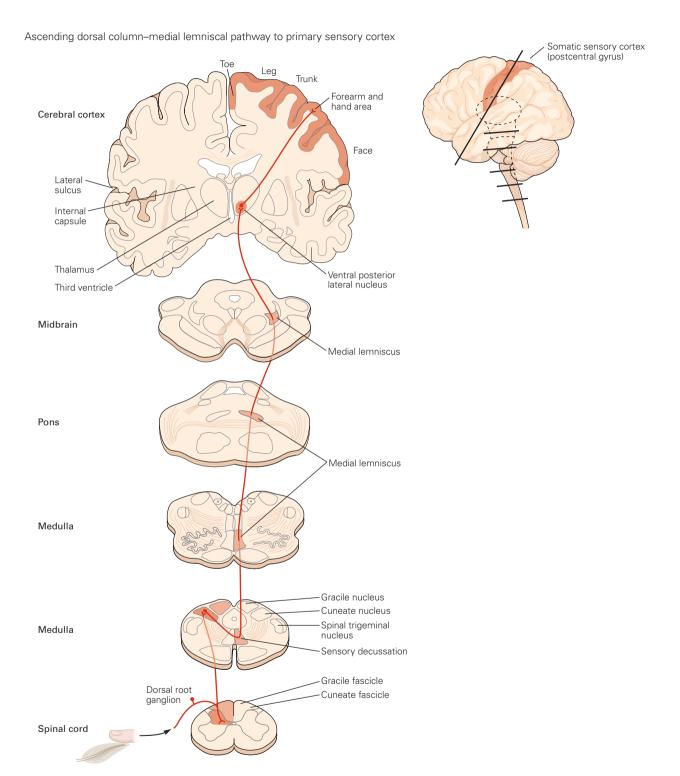

Figure 16–4 The medial lemniscus is a major afferent pathway for somatosensory information. Somatosensory information enters the central nervous system through the dorsal root ganglion cells. The flow of information ultimately leads

to excitation of the somatosensory cortex. Fibers that relay information from different parts of the body maintain an orderly relationship to each other and form a neural map of the body surface in their pattern of termination at each synaptic relay.

and their axons project to the primary somatosensory cortex (Figure 16–4). Other portions of the thalamus participate in motor functions, transmitting information from the cerebellum and basal ganglia to the motor regions of the frontal lobe.

Axons from cells of the thalamus that project to the neocortex travel in the internal capsule, a large fiber bundle that carries most of the axons running to and from the cerebral hemispheres. Through its connections with the frontal lobe, the thalamus may also play a role in cognitive functions, such as memory. Some nuclei that may play a role in attention project diffusely to large but distinctly different regions of cortex. The reticular nucleus, which forms the outer shell of the thalamus, does not project to the neocortex at all. Its largely inhibitory neurons receive inputs from other fibers as they exit the thalamus en route to the neocortex and in turn to the other thalamic nuclei.

The nuclei of the thalamus are most commonly classified into four groups—anterior, medial, ventrolateral, and posterior—with respect to the internal medullary lamina, a sheet-like bundle of fibers that runs the rostrocaudal length of the thalamus (Figure 16–5). Thus the medial group of nuclei is located medial to the internal medullary lamina, whereas the ventral and posterior

groups are located lateral to it. At the rostral pole of the thalamus the internal medullary lamina splits and surrounds the anterior group. The caudal pole of the thalamus is occupied by the posterior group, dominated by the pulvinar nucleus. Groups of neurons are also located within the fibers of the internal medullary lamina and are collectively referred to as the intralaminar nuclei.

The *anterior group* receives its major input from the mammillary nuclei of the hypothalamus and from the presubiculum of the hippocampal formation. The role of the anterior group is uncertain but thought to be related to memory and emotion. The anterior group is also interconnected with regions of the cingulate and frontal cortices.

The *medial group* consists mainly of the mediodorsal nucleus. This large thalamic nucleus has three subdivisions, each of which is connected to a particular portion of the frontal cortex. The nucleus receives inputs from portions of the basal ganglia, the amygdala, and midbrain and has been implicated in memory.

The nuclei of the *ventral group* are named according to their position within the thalamus. The ventral anterior and ventral lateral nuclei are important for motor control and carry information from the basal

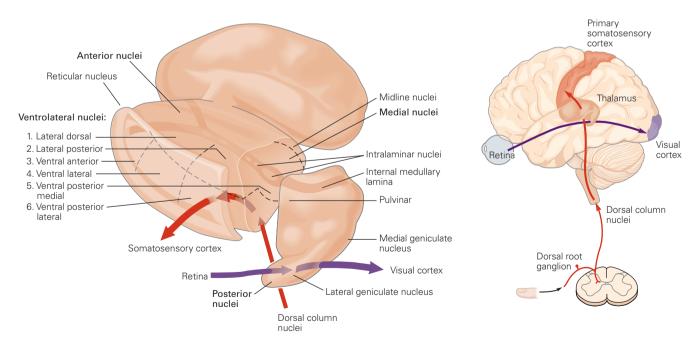

Figure 16–5 The major subdivisions of the thalamus. The thalamus is the critical relay for the flow of sensory information from peripheral receptors to the neocortex. Somatosensory information is conveyed from dorsal root ganglia to the ventral posterior lateral nucleus and from there to the primary

somatosensory cortex. Likewise, visual information from the retina reaches the lateral geniculate nucleus, which conveys it to the primary visual cortex in the occipital lobe. Each of the sensory systems, except olfaction, has a similar processing step within a distinct region of the thalamus.

ganglia and cerebellum to the motor cortex. The ventral posterior lateral nucleus conveys somatosensory information to the neocortex.

The posterior group includes the medial and lateral geniculate nucleus, lateral posterior nucleus, and the pulvinar. The medial and lateral geniculate nuclei are located near the posterior part of the thalamus. The medial geniculate nucleus is a component of the auditory system; it is organized tonotopically, and conveys auditory information to the superior temporal gyrus of the temporal lobe. The lateral geniculate nucleus receives information from the retina and conveys it to the primary visual cortex in the occipital lobe. The pulvinar is most enlarged in the primate brain, especially in the human brain, and its development seems to parallel the enlargement of the association regions of the parietal-occipital-temporal cortex (see Chapter 18). It has been divided into at least three subdivisions and is extensively interconnected with widespread regions of the parietal, temporal, and occipital lobes, as well as with the superior colliculus and other nuclei of the brain stem related to vision.

The thalamus not only projects to the visual areas of the neocortex but also receives extensive return inputs back from the neocortex. In fact, in the lateral geniculate nucleus the number of synapses formed by axons from the return projection from the occipital cortex is greater than the number of synapses that the lateral geniculate nucleus receives from the retina. Most nuclei of the thalamus receive a similarly prominent return projection from the cerebral cortex, although the functional significance of these projections is unclear.

The thalamic nuclei described thus far are called the relay (or specific) nuclei because they have a specific and selective relationship with a particular portion of the neocortex. Other thalamic nuclei, called nonspecific nuclei, project to several cortical and subcortical regions. These nuclei are located either on the midline of the thalamus (the midline nuclei) or within the internal medullary lamina (the intralaminar nuclei). The largest of the midline nuclei are the paraventricular, parataenial, and reuniens nuclei; the largest of the intralaminar cell groups is the centromedian nucleus. The intralaminar nuclei project to medial temporal lobe structures, such as the amygdala and hippocampus, but also send projections to components of the basal ganglia. These nuclei receive inputs from a variety of sources in the spinal cord, brain stem, and cerebellum and are thought to mediate cortical arousal and perhaps to participate in the integration of sensory submodalities that we shall learn about in Chapters 21 and 22.

Finally, the outer covering of the thalamus is formed by a unique sheet-like structure, the *reticular*

nucleus. The majority of its neurons use the inhibitory transmitter γ -aminobutyric acid (GABA), whereas most of the neurons in the other thalamic nuclei use the excitatory transmitter glutamate. Moreover, the neurons of the reticular nucleus are not interconnected with the neocortex. Rather, their axons terminate on the other nuclei of the thalamus. These other nuclei also provide the input to the reticular nucleus via collaterals of their axons that exit the thalamus through the reticular nucleus. Thus the reticular nucleus modulates activity in other thalamic nuclei based on its monitoring of the entirety of the thalamocortical stream of information. This portion of the thalamus thus acts like a filter that gates information flow to the neocortex.

We see, then, that the thalamus is not a passive relay station where information is simply passed on to the neocortex. Rather it is a complex brain region where substantial information processing is possible. To give but one example, the output of somatosensory information from the ventral posterior lateral nucleus is subject to four types of processing: (1) local processing within the nucleus; (2) modulation by brain stem inputs, such as the noradrenergic and serotonergic systems; (3) inhibitory feedback from the reticular nucleus; and (4) excitatory feedback from the neocortex.

Sensory Information Processing Culminates in the Cerebral Cortex

Somatosensory information from the ventral posterior lateral nucleus is conveyed mainly to the primary somatosensory cortex (Brodmann's area 3b). The neurons here are exquisitely sensitive to tactile stimulation of the skin surface. As in subcortical synaptic centers of the somatosensory system, the neurons in different parts of the cortex are somatotopically organized.

When the neurosurgeon Wilder Penfield stimulated the surface of the somatic sensory cortex in patients undergoing brain surgery, he found that sensation from the lower limbs is mediated by neurons located near the midline of the brain, whereas sensations from the upper body, hands and fingers, the face, lips, and tongue are mediated by neurons located laterally. As we shall learn in more detail in Chapter 17, Penfield found that although all parts of the body are represented in the cortex somatotopically, the area of cortex devoted to each body part is not proportional to its mass. Instead, it is proportional to the density of innervation, which translates to the fineness of discrimination in the body part. Thus the area of cortex devoted to the fingers is larger than that for the arms.

Likewise, the representation of the lips and tongue occupies more cortical surface than that of the remainder of the face (Figure 16–6).

The cerebral cortex is organized functionally into columns of cells extend from the white matter to the surface of the cortex. The cells in each column comprise a computational module with a highly specialized function. The larger the area of cortex dedicated to a function, the greater the number of computational columns that are dedicated to that function (see Chapter 19). The highly discriminative sense of touch in the fingers is a result of the large area of cortex dedicated to processing somatosensory information from the hand.

A second major insight from the early electrophysiological studies was that the somatosensory cortex contains not one but several somatotopic arrays of inputs from the skin and therefore several neural maps of the body surface. The primary somatosensory cortex (anterior parietal cortex) has four complete maps of the skin, one each in areas 3a, 3b, 1, and 2. Basic processing of tactile information takes place in area 3, whereas more complex or higher-order processing occurs in area 1. In area 2 tactile information is combined with

information concerning limb position to mediate the tactile recognition of objects. Neurons in the primary somatosensory cortex project to neurons in adjacent areas, and these neurons in turn project to other adjacent cortical regions (Figure 16–7). At higher levels in the hierarchy of cortical connections somatosensory information is used in motor control, eye—hand coordination, and memory related to touch.

The cortical areas involved in the early stages of sensory processing are concerned only (or primarily) with a single modality. Such regions are called unimodal association areas. Information from the unimodal association areas converges on multimodal association areas of the cortex concerned with combining sensory modalities. As we shall learn in the next two chapters and again in Chapter 62, these multimodal associational areas, which are heavily interconnected with the hippocampus, appear to be particularly important for two tasks: (1) the production of a unified percept and (2) the representation of the percept in memory.

Thus, from the mechanical pressure on a receptor in the skin to the perception that a finger has been touched by a friend shaking your hand, somatosensory

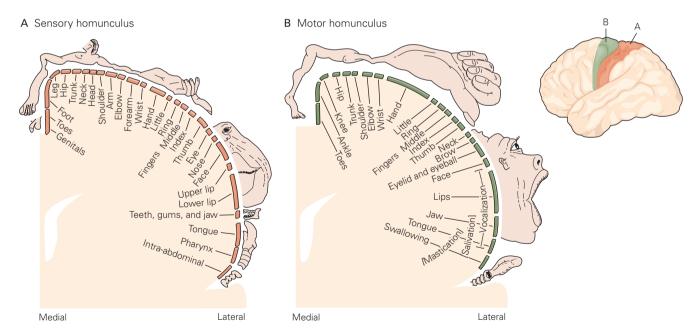

Figure 16–6 A homunculus illustrates the relative amounts of cortical area dedicated to individual parts of the body. (Adapted, with permission, from Penfield and Rasmussen 1950.)

A. The entire body surface is represented in an orderly array of somatosensory inputs in the cortex. The area of cortex dedicated to processing information from a particular part of the body is not proportional to the mass of the body part but

instead reflects the density of sensory receptors in that part. Thus sensory input from the lips and hands occupies more area of cortex than, say, that from the elbow.

B. Output from the motor cortex is organized in similar fashion. The amount of cortical surface dedicated to a part of the body is related to the degree of motor control of that part. Thus in humans much of the motor cortex is dedicated to moving the muscles of the fingers and the muscles related to speech.

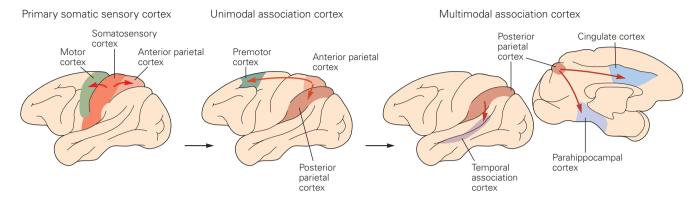

Figure 16–7 The processing of sensory information in the cerebral cortex begins with primary sensory areas, continues in unimodal association areas, and is completed in multimodal association areas. Sensory systems also communicate with portions of the motor cortex. For example, the primary somatosensory cortex projects to the motor area in the frontal lobe and to the somatosensory association area

in the parietal cortex. The somatosensory association area, in turn, projects to higher-order somatosensory association areas and to the premotor cortex. Information from different sensory systems converges in the multimodal association areas, which include the parahippocampal, temporal association, and cingulate cortices.

information is processed in serial and parallel pathways from the dorsal root ganglia to the somatosensory cortex, to unimodal association areas, and finally to multimodal association areas. One of the primary purposes of somatosensory information is to guide directed movement. As one might imagine, there is a close linkage between the somatosensory and motor functions of the cortex.

Voluntary Movement Is Mediated by Direct Connections Between the Cortex and Spinal Cord

As we shall see in Chapter 18 a major function of the perceptual systems is to provide the sensory information necessary for the actions mediated by the motor systems. The primary motor cortex is organized somatotopically like the somatic sensory cortex (Figure 16–6B). Specific regions of the motor cortex influence the activity of specific muscle groups.

The axons of neurons in layer V of the primary motor cortex project through the corticospinal tract to the ventral horn of the spinal cord. The human corticospinal tract consists of approximately one million axons, of which approximately 40% originate in the motor cortex. These axons descend through the subcortical white matter, the internal capsule, and the cerebral peduncle in the midbrain (Figure 16–8). In the medulla the fibers form prominent protuberances on the ventral surface called the medullary pyramids, and thus the entire projection is sometimes called the pyramidal tract.

Like the ascending somatosensory system, the descending corticospinal tract crosses to the opposite side of the spinal cord. Most of the corticospinal fibers cross the midline in the medulla at a location known as the pyramidal decussation. However, approximately 10% of the fibers do not cross until they reach the level of the spinal cord at which they will terminate. The corticospinal fibers make monosynaptic connections with motor neurons, connections that are particularly important for individuated finger movements. They also form synapses with interneurons in the spinal cord. These indirect connections are important for coordinating larger groups of muscles in behaviors such as reaching and walking.

The motor information carried in the corticospinal tract is significantly modulated by both sensory information and information from other motor regions. A continuous stream of tactile, visual, and proprioceptive information is needed to make voluntary movement both accurate and properly sequenced. In addition, the output of the motor cortex is under the substantial influence of other motor regions of the brain, including the cerebellum and basal ganglia, structures that are essential for smoothly executed movements. These two subcortical centers provide feedback essential for the smooth execution of skilled movements and thus are also important for motor learning, the improvement in motor skills through practice (Figure 16–9, and see Chapter 65).

The cerebellum receives somatosensory information directly from primary afferents originating in the spinal cord as well as from corticospinal axons descending

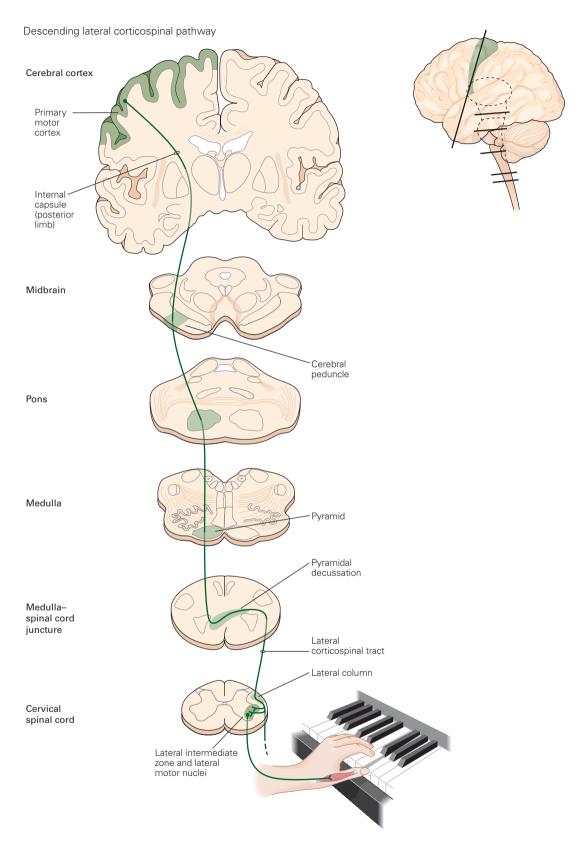

Figure 16–8 Fibers that originate in the primary motor cortex and terminate in the ventral horn of the spinal cord constitute a significant part of the corticospinal tract.

The same axons are at various points in their projection part of the internal capsule, the cerebral peduncle, the medullary pyramid, and the lateral corticospinal tract.

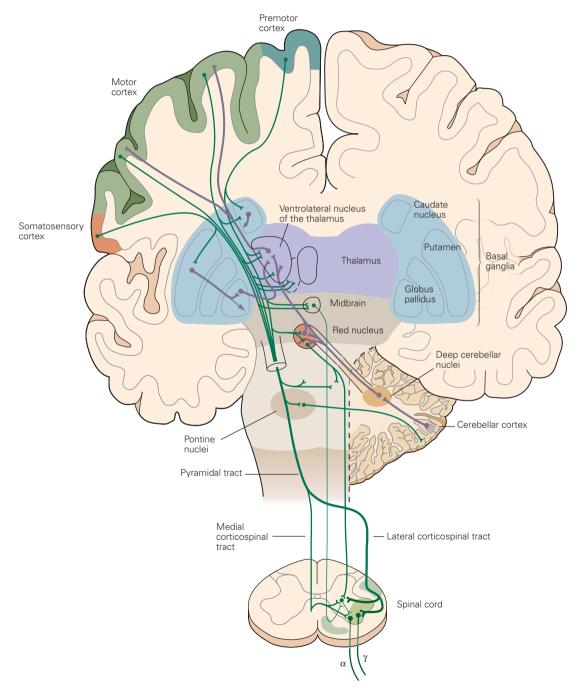

Figure 16–9 Voluntary movement requires coordination of all components of the motor system. The principal components are the motor cortex, basal ganglia, thalamus, midbrain, cerebellum, and spinal cord. The principal descending projections are shown in green; feedback projections and local connections are shown in purple. All of this processing is

incorporated in the inputs to the motor neurons of the ventral horn of the spinal cord, the so-called "final common pathway" that innervates muscle and elicits movements. (This figure is a composite view made from sections of the brain taken at different angles.)

from the neocortex. The cerebellum is thought to be part of an error-correcting mechanism for movements because it can compare movement commands from the cortex with somatic sensory information about what actually happened. Thus the cerebellum is thought to be important in "predictive control" of movements, in which commands for movements are adjusted based on information about the effectiveness of prior movement. In addition, as muscles get stronger with exercise and as our bodies grow, the neural signals for a particular movement must change, as they must if muscles are damaged. The cerebellum enables motor control systems to adapt motor commands to the changing condition of the musculature so that, for example, a weakened arm will not undershoot its goal or a stronger arm overshoot.

The cerebellum can influence posture and movement through its connections in the brain stem motor nuclei, which can directly modulate spinal motor circuits. However, the major influence of the cerebellum on movement is through its connections in the ventrolateral nuclei of the thalamus, which connect directly to the motor and premotor cortex.

The basal ganglia are a collection of subcortical nuclei (see Figure 16–9) that receive direct projections from much of the neocortex, including sensory, motor, and premotor areas, and those parts of association cortex that are important for motivation, cognition, and emotion. The output nuclei of the basal ganglia send signals to regions of the thalamus that project to the cerebral cortex. Although the functions of the basal ganglia have remained surprisingly elusive, dysfunction of the basal ganglia results in particularly striking disorders of movement characteristic of Parkinson disease (tremor at rest, rigidity, and disinclination to move) and of Huntington disease (choreiform movements).

Thus an important consequence of basal ganglia dysfunction is that the abnormal signals sent to cortical motor areas have a major, negative, impact on motor output. Indeed, cortical lesions that limit voluntary movements associated with disorders of the basal ganglia. This capacity of the basal ganglia to create marked disorders of movement when they are functioning abnormally must in some way be matched by a similar profound influence over normal motor function.

An Overall View

Sensory and motor information is processed in the brain in a variety of discrete pathways that are active simultaneously. A functional pathway is formed by the serial connection of identifiable groups of neurons, and each group processes more complex or specific information than the preceding group. Thus different pathways that run through the spinal cord, brain stem, and into the cortex mediate the sensations of touch and pain. All sensory and motor systems follow the pattern of hierarchical and parallel processing.

As we shall see in later chapters, contrary to an intuitive analysis of our personal experience, perceptions are not precise copies of the world around us. Sensation is an abstraction, not a replication, of reality. The brain constructs an internal representation of external physical events after first analyzing various features of those events. When we hold an object in the hand, the shape, movement, and texture of the object are simultaneously but separately analyzed according to the brain's own rules, and the results are integrated in a conscious experience.

How this integration occurs—the *binding problem*—and how conscious experience emerges from the brain's selective attention to incoming sensory information are two of the most pressing questions in cognitive neural science.

Selective Attention to Visual Stimuli Can Be Studied on the Cellular Level in Nonhuman Primates

How Is Self-Awareness Encoded in the Brain?

An Overall View

is necessary to understand how the brain works. Considering that the brain has a hundred billion nerve cells, it is remarkable how much can be learned about mental activity by examining one nerve cell at a time. Progress is particularly good

when we understand the anatomy and connections of functionally important pathways.

Cellular studies of the sensory systems, for example, provide important insight into how stimuli at the body's surface are translated by the brain into sensations and planned action. In the visual system, the sensory system most thoroughly studied at the cellular level, information arrives in the brain from the retina in parallel pathways dedicated to analyzing different aspects of the visual image—form, movement, and color. These separate inputs are eventually integrated into coherent images according to the brain's own rules, rules that are embodied in the circuitry of the visual system.

Different modalities of perception—an object seen, a face touched, or a melody heard—are processed similarly by the different sensory systems. Receptors in each system first analyze and deconstruct stimulus information. Receptors at the periphery of the body for each system are sensitive to a particular kind of physical event—light, pressure, tone, or chemical odorants. When a receptor is stimulated—when, for example, a receptor cell in the retina is excited by light—it responds with a distinct pattern of firing that represents certain properties of the stimulus. Each sensory system obtains information about the stimulus in this way and this information is conveyed along a pathway of cells leading to a specific (unimodal) region of cerebral cortex. In the cortex different unimodal regions representing different sensory modalities communicate with multimodal association areas through specific intracortical pathways, and in this network signals are selected and combined into an apparently seamless perception.

The brain thus produces an integrated perception because nerve cells are wired together in precise and orderly ways according to a general plan that does not vary greatly among normal individuals. Nevertheless, the connections are not exactly the same in all individuals. As we shall learn in later chapters, connections between cells can be altered by activity and by learning. We remember specific events because the structure and function of the connections between nerve cells are modified by those events.

Despite its success, neural scientists believe that a cellular approach alone is not sufficient for understanding how the integrative action of the brain—the simultaneous activity of discrete sets of neurons—produces cognition. For this task the brain must be studied as an information processing organ. This is the approach of *cognitive neural science*, which uses a combination of methods from a variety of fields—cell biology, systems neural science, brain imaging, cognitive psychology, behavioral neurology, and computational neuroscience.

Ulric Neisser, one of the pioneers of cognitive psychology, defined the challenge of this field in the following terms:

It has been said that beauty is in the eye of the beholder. As a hypothesis . . . it points clearly enough to the central problem of cognition—the world of experience is produced by the man who experiences it There certainly is a real world of trees and people and cars and even books, and it has a great deal to do with our experience of these objects. However, we have no direct immediate access to the world, nor to any of its properties. . . .

Whatever we know about reality has been mediated not only by the organs of sense but by complex systems which interpret and reinterpret sensory information. . . . The term "cognition" refers to all the processes by which the sensory input is transformed, reduced, elaborated, stored, recovered and used. . . .

In this chapter we first discuss how cognitive neural science evolved from otherwise disparate disciplines. We illustrate the success of the approach by considering what has been learned about one complex mental state: the experience of personal and extrapersonal space, both real and imagined. We then discuss how the unconscious and conscious mental processes are modeled by cognitive neural science. A great deal of cognitive processing goes on unconsciously. Sigmund Freud likened the conscious perception of mental processes to the perception of the external world by sense organs. We also discuss the profound challenges to a scientific study of consciousness. The five major subjects of cognitive neural science—perception, action,

emotion, language, and memory—are discussed in detail in the subsequent five parts of the book beginning with Chapter 21.

The Major Goal of Cognitive Neural Science Is to Understand Neural Representations of Mental Processes

Until the end of the 19th century the chief method for understanding the mind was introspection. In fact, the scholarly study of the mind was a branch of philosophy. By the middle of the 19th century, however, the philosophical approach was giving way to empirical analysis and eventually the formation of the independent discipline of experimental psychology. In its early years experimental psychology was concerned primarily with the sequence of events by which an external stimulus becomes an internal sensation. By the end of the 19th century the interests of psychologists turned to how behavior is generated, how it is modified by learning and attention, and how it is stored in memory.

The discovery of simple experimental ways of studying learning and memory—first in human beings by Hermann Ebbinghaus in 1885 and a few years later in experimental animals by Ivan Pavlov and Edgar Thorndike—led to a rigorous empirical school of psychology called *behaviorism*. Behaviorists, notably J. B. Watson and B. F. Skinner in the United States, argued that behavior could be studied with the precision of the physical sciences, but only if psychologists abandoned speculation about what occurs in the mind and focused exclusively on the observable aspects of behavior. For example, the behaviorists argued that one cannot base a psychology on the idea that people do certain things because they believe they are the right things to do or because they want to do them.

Behaviorists regarded these unobservable mental processes, especially anything as abstract as motivations, feeling, or conscious awareness, as inaccessible to scientific study. They concentrated instead on evaluating—objectively and precisely—the relationship between specific physical stimuli and observable responses in intact animals. Their early successes in studying simple forms of behavior and learning encouraged them to treat all cognitive processes that intervene between the stimulus (input) and behavior (output) as irrelevant.

During behaviorism's most influential period, in the 1950s, many psychologists accepted the most radical behaviorist position: that observable behavior is all there is to mental life. As a result, the scientific concept of behavior largely depended on the techniques used to study it. This emphasis reduced the domain of experimental psychology to a restricted set of problems and excluded some of the most fascinating features of mental life.

By the 1960s it was not difficult for the founders of cognitive psychology—notably Edwin Tolman, Frederick Bartlett, George Miller, Noam Chomsky, Ulric Neisser, and Herbert Simon—to convince the scientific community that behaviorism was too limiting Building on earlier evidence from Gestalt psychology, psychoanalysis, and neurology, these early cognitive psychologists sought to demonstrate that our knowledge of the world is based on our biological equipment for perceiving the world, that perception is a constructive process that depends not only on the stimulus but also on the mental apparatus of the perceiver—the organization of the sensory and motor systems in the brain. We now realize that this constructive process also involves emotion, motivation, and reward.

What ultimately distinguished the cognitivists from the behaviorists was not only their conceptual approach to behavior but also the complexity of the methods they used. Cognitivists realized that only relatively few input—output relationships are stereotyped, that these relationships vary significantly because of mental states, past history, and expectations, the very factors that the behaviorists tended to ignore. Thus these variables must also be observable in behavior (or *output*) but are just more difficult to identify than the behavior defined by behaviorists.

This new perspective relied on neural network modeling and fortunately it coincided with the emergence of large-scale computers in the period following World War II. Computers allowed the modeling and testing of ideas about large neural networks that in principle are capable of higher mental functions. However, once psychologists acknowledged that mental activity was equivalent to computational processes in the brain, they had to face the fact that most mental processes were still largely inaccessible in living subjects. Without direct access to the brain, it would be difficult if not impossible to choose between various rival theories.

Fortunately, new tools for the empirical study of mental processes quickly became available, and significant progress was soon made in cellular analyses of the neural mediation of vision, touch, and action in intact primates engaged in ordinary behavior. Single-neuron recording and noninvasive imaging and recording techniques have allowed researchers to describe how neural activity in different sensory and motor pathways encodes sensory stimuli and planned actions. Moreover, imaging methods permit direct visualization of the brain in human subjects engaged in mental activity, allowing insight into attention and

aspects of consciousness under controlled conditions (Chapter 20). Thus we can now study directly neural representations of the environment and motor action by comparing cellular recordings in primates engaged in purposeful activity with imaging of the human brain at work.

Cognitive neural science, as now practiced, emerged from four major technical and conceptual developments. First, in the 1960s and 1970s techniques were developed by Robert Wurtz and Edward Evarts at the National Institutes of Health for studying the activity of single cells in the brains of animals, including primates, engaged in controlled behavior in the laboratory. This allowed investigators to correlate the activity of specific populations of neurons with specific perceptual and motor processes. From these microelectrode studies we have been able to see that the mechanisms of perception are much the same in humans, monkeys, and even simpler animals.

These cellular studies in monkeys also made it possible to identify the importance of different combinations of areas of the brain involved in specific cognitive functions, such as attention and decision-making. These approaches changed the way the biology of behavior is studied both in experimental animals and in humans.

Second, developments in neural science and cognitive psychology stimulated a renewed interest in the behavioral analysis of patients with brain lesions that interfere with mental functioning. This area, neuropsychology, had remained a strong subspecialty of neurology in Europe but was neglected for a time in the United States. Lesions of different regions of the brain can result in quite specific cognitive deficits. The behavioral consequences of brain lesions thus tell us much about the function of specific neural pathways. Lesion studies have shown that cognition is the product of several specialized systems, each with many components. For example, the visual system has specialized pathways for processing information about color and form on the one hand and movement on the other.

Third, the development of imaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (MRI), as well as the development of magnetoencephalography, has made it possible to relate changes in the activity of large populations of neurons to specific mental acts in living humans (see Chapter 20). This advance has been paralleled by two further developments. The use of voltage and calcium-sensitive dyes has permitted the study of neuronal activity in large ensembles of neurons, both in vitro and in the brains of behaving animals. The more

recent use of light-sensitive ion channels has permitted the activation or inactivation of the activity of specific neurons or groups of neurons in the neural circuits of intact behaving animals.

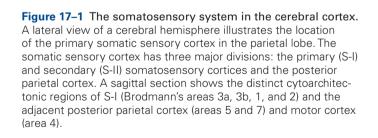

Finally, improvement in computers and the emergence of a powerful subdiscipline of computational neural science has made it possible to model the activity of large populations of neurons and to test ideas about the roles of specific components of neural circuits in the brain in particular behaviors. To understand the neural organization of a complex behavior like speech we must understand not only the properties of individual cells and pathways but also the network properties of circuits in the brain. Although network properties depend on the properties of individual neurons in the network, they are not identical or even similar to those properties but are an *emergent* property of the way those different cells are interconnected.

When computational approaches are combined with detailed behavioral studies, for example with the psychophysical study of a specific perceptual act, the combined analysis can help to characterize the properties of a system. Thus psychophysics can describe what

the system is capable of doing whereas computational modeling can describe how the properties of constituent cells could account for system properties of the neural circuits involved (see Appendices E and F).

The work of cognitive and computational neuroscientists is providing enormous insight into the workings of the brain. However, it also raises a difficult set of questions about the relationship between observed neurophysiological and mental processes, and particularly between these cellular biological processes and consciousness. The answers to these questions are yet unknown, but the mere fact that scientists are addressing them is a major advance.

To illustrate how cognitive neural science describes a mental act, in the next few sections we summarize what neural science has learned about the brain's representation of personal space (one's body) and peripersonal space, the space within arm's length ("near space"). We shall see how the brain constructs mental representations of space from external sensory input; how this representation gives rise to imagined and remembered space; and how it is selected by action, modified by normal experience, and distorted by

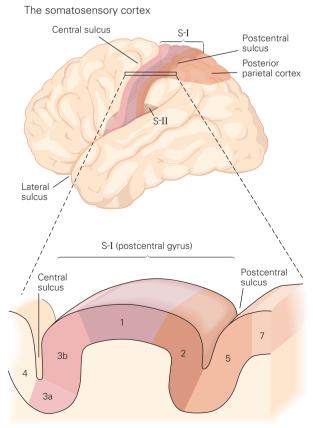

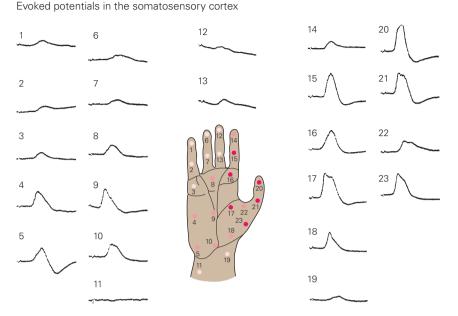

Figure 17–2 Evoked potentials in the somatosensory cortex elicited by stimulation of the hand. The evoked potentials shown here are the summed activity of one large group of neurons in the left postcentral gyrus of a monkey, elicited by a light touch at different points on the right palm. The evoked potentials were strongest when the thumb or forefinger was stimulated (points 15, 16, 17, 20, 21, and 23) and weakest when the middle or small finger was stimulated (points 1, 2, 3, 12, and 13). (Adapted, with permission, from Marshall, Woolsey, and Bard 1941.)

abnormal experience such as loss of a body part. This discussion illustrates a key principle that we will consider again in Chapter 19, that action has a key role in perception. The cognitive functions of the premotor areas provide for flexibility in behavior, preventing an otherwise stereotypic relationship between sensory input and behavioral output. By interpreting sensory input based on experience and mental state, these cognitive premotor processes shape our behavior.

The neural representation of space is most clearly evident in the early stages of sensory processing—in primary and higher-order areas of somatosensory cortex—where it takes the form of a map of the tactile sensors on the body surface. We shall see how this map can be modified after the loss of a body part and how those modifications can create a phantom representation. We shall also see how representations of personal and peripersonal space differ from extrapersonal space, the space beyond arm's length ("far space"), and how representations of extrapersonal space can give rise to imagined and remembered space.

The Brain Has an Orderly Representation of Personal Space

The neural representation of the body surface is a simple example of an internal representation, one that has been extensively explored in the study of touch and proprioception. Touch provides information about the

properties of objects, such as their shape, texture, and solidity; proprioception provides information about the static position and movement of fingers and limbs.

An internal representation can be thought of as a certain pattern of neural activity that has at least two aspects: (1) the pattern of activation within a particular population of neurons (some cells are active and others not) and (2) the pattern of firing in individual cells.

Sensory neurons with receptors in the skin translate the mechanical energy of a stimulus into neural signals that are then conveyed along pathways that end in the somatosensory areas of the parietal lobe of the cerebral cortex (Figure 17–1). Each pathway includes one or more synaptic relays. At each relay, where thousands of afferent axons terminate on a cluster of similar neurons, the arrangement of the presynaptic fibers preserves the spatial relations of the receptors on the body surface. This somatotropic order thus creates a neural map of the body surface at each synaptic relay in the somatosensory system—information from neighboring receptors in the skin is conveyed to neighboring cells in each synaptic relay.

Neural maps of the body surface were first detected in laboratory animals using gross recording and stimulation techniques on the surface of the postcentral gyrus of the parietal cortex, the only portion of the cortex accessible with the experimental techniques available at that time. In the late 1930s Wade Marshall found that he could produce an evoked potential in the cortex by touching a specific part of the animal's body surface (Figure 17–2). Evoked potentials are electrical signals

that represent the summed activity of thousands of cells and are recorded with external macroelectrodes on the brain surface. The evoked response method was used by Marshall, Clinton Woolsey, and Phillip Bard to map the neural representation of the body surface in the postcentral gyrus of monkeys (Figure 17–3).

The human somatosensory cortex was similarly mapped in the late 1940s by the Canadian neurosurgeon Wilder Penfield during operations for epilepsy and other brain disorders. Working with locally anesthetized conscious patients, Penfield stimulated various points on the surface of the postcentral gyrus

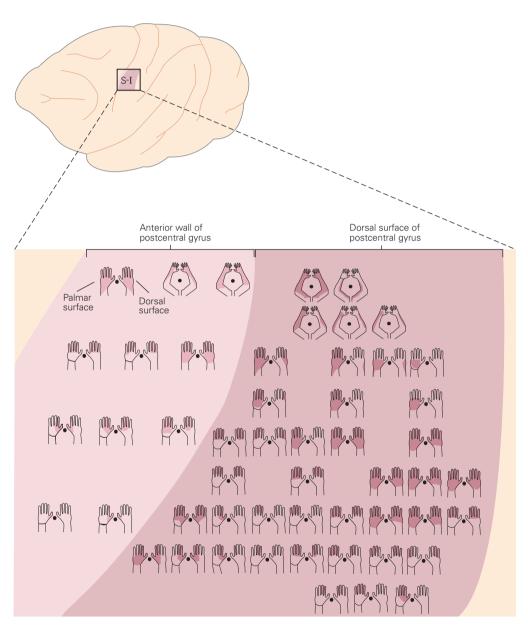

Figure 17–3 An early map of the representation of the hands in the monkey cortex. Recordings were made in the primary somatic sensory cortex (S-I) in the postcentral gyrus. The lateral view of the brain shows the recording site. Sites in Brodmann's areas 3b and 1 that responded to stimulation of the palmar and dorsal surfaces of the right hand are identified by black dots in a schematic map of these areas. The area of

the hand that evoked a response at each site is indicated by the **colored portion** of the hand. The sites in the anterior wall of the postcentral gyrus are roughly in areas 3b and 3a (see Figure 17–1). The sites on the dorsal surface of the postcentral gyrus are roughly in area 1. (Adapted, with permission, from Marshall, Woolsey, and Bard 1941.)

and asked the patients to report what they felt. This procedure was necessary to ascertain where the epilepsy started and therefore to avoid damage to healthy brain tissue during surgery. Penfield found that activation of specific populations of cells in the postcentral gyrus reasonably simulated natural activation of these populations, producing sensations of touch and pressure in the contralateral hand or leg. From these studies Penfield constructed the neural map of the human body in the primary somatosensory cortex.

In this map the leg is represented in the most medial area of cortex followed by the trunk, arms, face, and finally, most laterally, the teeth, tongue, and esophagus. The area devoted to each part of the body reflects the relative importance of that part in sensory perception. Thus the area for the face is large compared with that of the back of the head, that of the index finger is gigantic compared with the big toe, and the torso is represented in the smallest area of all (Figure 17–4).

Sensory homunculus

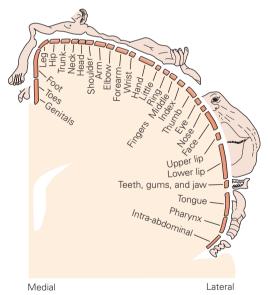

Figure 17–4 Cortical representations of the parts of the body correspond to the sensory importance of each part. Each of the four areas of the somatosensory cortex forms its own map of the body (see Figure 17–6). The sensory homunculus illustrated here is based on the body map in area 1 in the postcentral gyrus. This area receives inputs from tactile receptors in the skin throughout the body. Areas of cortex representing parts of the body that are especially important for tactile discrimination, such as the tip of the tongue, fingers, and hand, are disproportionately large, reflecting the greater degree of innervation in these parts. (Adapted, with permission, from Penfield and Rasmussen 1950.)

Such differences reflect differences in innervation density throughout the body. Similar relationships are observed in other animals. In rabbits, for example, the face and snout have the largest cortical representation because they are the most important sensory surfaces a rabbit uses to explore its environment (Figure 17–5).

The Cortex Has a Map of the Sensory Receptive Surface for Each Sensory Modality

Marshall went on to find that the receptive surfaces for vision and hearing, the retina and the cochlea, are also represented topographically in the cortex. Marshall's early efforts to analyze these sensory maps of the body probed only limited areas of the cortex and used techniques with poor spatial resolution. His work in the area of touch led to the conclusion that there is a single large representation of the body surface in the cerebral cortex. Later studies based on single-neuron recordings revealed four fairly complete maps in the four areas of the primary somatosensory cortex (Figure 17–6).

Although each of the four areas has essentially the same body map, each area processes a distinct type of information. Area 3a receives information from muscles and joints, important for limb proprioception. Area 3b receives information from the skin, important for touch. This information from the skin is further processed within area 1 and then combined with information from muscles and joints in area 2. This explains why a small lesion in area 1 impairs tactile discrimination, whereas a small lesion in area 2 impairs the ability to recognize the shape of a grasped object.

Cortical Maps of the Body Are the Basis of Accurate Clinical Neurological Examinations

The existence in the brain of maps of the sensory receptive surface and a similar motor map for movement explains why clinical neurology can be an accurate diagnostic discipline, even though for many decades before brain imaging came along neurology relied on only the simplest tools: a wad of cotton, a safety pin, a tuning fork, and a rubber reflex hammer. For example, disturbances in the somatic sensory system can be located with remarkable accuracy because there is a direct relationship between the anatomical organization of the functional pathways in the brain and specific perceptual and motor behaviors.

A dramatic example of this relationship is the Jacksonian march, a characteristic sensory seizure first

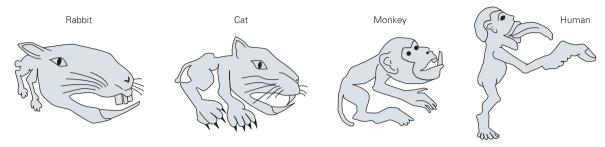

Figure 17–5 Cortical somatosensory maps in different species reflect different somatic sensibilities. These drawings show the relative importance of body regions in the somatosensory

cortex of four species, based on evoked potentials in the thalamus and cortex.

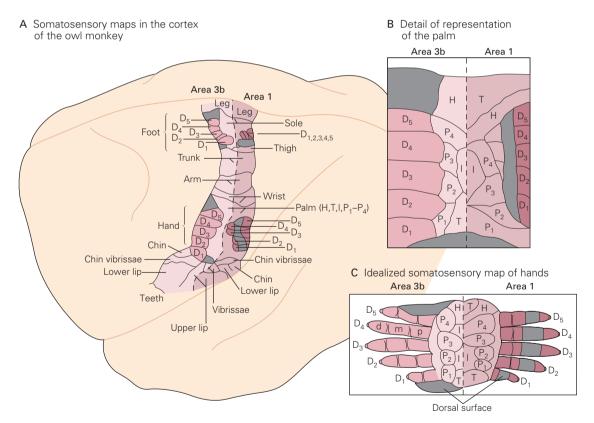

Figure 17–6 Each of the four areas of the primary somatic sensory cortex forms its own complete representation of the body surface. (Adapted with permission, from Kaas et al. 1981.)

A. Somatosensory maps of the body in Brodmann's areas 3b and 1 are shown in this dorsolateral view of the brain of an owl monkey. The two maps are roughly mirror images. Each digit of the hands and feet is individually represented (D_1 to D_5). Areas 2 and 3a (not shown) have a similar organization.

B. This more detailed illustration of the representation of the palm in areas 3b and 1 shows discrete areas of representation of the palmar pads (P_4 to P_1), two insular pads (I), two hypothenar pads (H), and two thenar pads (T).

C. This idealized representation of the hands in the somatosensory cortex is based on studies of a large number of monkeys. The areas of cortex devoted to the palm and digits reflect the extent of innervation of each part of the hand. The five digital pads $(D_1 \text{ to } D_6)$ include distal, middle, and proximal segments (d, m, p).

described by the British neurologist John Hughlings Jackson. In this type of seizure there is, in addition to a motor progression, a sensory progression. Numbness and paresthesia (inappropriate sensations such as burning or prickling) begin in one place and spread throughout the body. For example, numbness might start at the fingertips, spread to the hand, up the arm, across the shoulder into the back, and down the leg on the same side. This sequence is explained by the arrangement of inputs from the body in the somatosensory cortex (Figure 17–4); the seizure starts in the lateral region of the cortex, in the area where the hand is represented, and propagates across the cortex toward the midline.

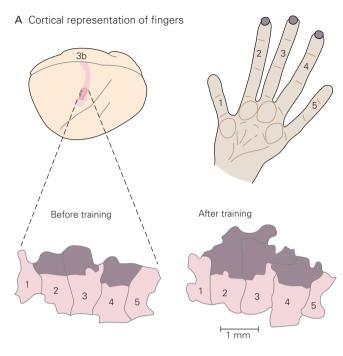

The Internal Representation of Personal Space Can Be Modified by Experience

Until recently it was thought that the sensory maps of the body surface in the cortex were hard-wired, and the pathways from the receptors in the skin to the cortex are fixed early in development. But cortical maps do change, even in adults, and details of these maps vary considerably from one individual to another.

To show that experience can account for this variability, owl monkeys were trained to touch a rotating disk with the tips of the middle fingers to obtain food. After several months of touching the disk, the area of cortex devoted to the tips of the middle fingers was greatly expanded, whereas that devoted to the adjacent proximal phalanges, which had not been used in the experiment, was correspondingly reduced (Figure 17–7). These results demonstrate that use of the fingertips can strengthen connections between neurons along the somatosensory pathway from skin to cortex.

Dramatic changes in afferent connections can also occur because of disuse. In one study of several monkeys an upper limb was rendered completely useless by severing all sensory nerves to the arm. The animals were monitored for 10 or more years. In all these monkeys the representation of the face, where innervation remained intact, expanded into the adjacent area of cortex that had represented the hand before deafferentation. As a result, stimulation of the face evoked responses in the area of cortex that normally represented the hand. These changes occurred in a wide area of cortex: A third of the entire body map was taken over by new connections from the face.

How do these changes occur? Afferent connections to neurons in the somatic sensory cortex are thought to be fine-tuned during development when the firing of pre- and postsynaptic cells is correlated. Cells that

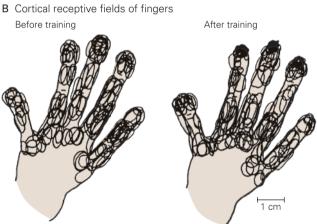

Figure 17–7 Increased use of a finger enlarges the cortical representation of that finger. (Adapted, with permission, from Jenkins et al. 1990.)

A. The regions in cortical area 3b representing the surfaces of the digits of an adult monkey are shown 3 months before training and after training. During training the monkey performed a task that required use of the tips of the distal phalanges of digits 2, 3, and occasionally 4 for 1 hour per day. After training there is a substantial enlargement of the cortical representation of the stimulated fingers (purple).

B. All receptive fields on the surfaces of the digits were identified before and after training to determine recording sites within area 3b. The receptive field for a cortical neuron is the area on the skin where a tactile stimulation either excites or inhibits a cell. Training increased the number of receptive fields in the distal tips of the phalanges of digits 2, 3, and 4.

fire together are thought to strengthen their connection together. Michael Merzenich and his colleagues tested this idea by surgically connecting the skin of two adjacent fingers of a monkey. This procedure assures that the connected fingers are always used together and therefore increases the correlation of their inputs from the skin. Increasing the correlation of activity from adjacent fingers in this way abolishes the sharp discontinuity normally evident between the zones in the somatosensory cortex that receive inputs from these digits. Thus, although patterns of connections are genetically programmed, they are also modified by experience.

Magnetic encephalography, a method for recording the magnetic field produced by local electrical activity, has been used to construct cortical maps of the hand with a precision of millimeters (Figure 17–8). This technique has been used to compare the hand area in the cortex of normal adult humans with that of patients with a congenital fusion of the fingers (syndactyly). Patients with this syndrome do not have individual fingers—their hand is like a fist—so that neural activity in one part of the hand is always correlated with activity in all the other parts. The representation in the cortex of the syndactylic hand is considerably less than that of a normal person, and within this shrunken representation the neurons that receive signals from the fingers are not organized somatotopically (Figure 17–9A).

When the fingers of one syndactylic patient were surgically separated, however, each newly separate finger became individually represented in the cortex within weeks. The new neural organization occupied an

area of cortex closely corresponding to that of normal individuals, with normal distances between each digit (Figure 17–9B).

These results raise an important question that is even more urgent in the study of phantom limbs. How are changes in cortical maps interpreted by the brain, and how do they shape perception? Many patients with amputated limbs continue to have a vivid sensory experience of the missing limb, a disorder known as the *phantom limb syndrome*. The patient senses the presence of the missing limb, feels it move around, and even feels it try to shake hands when greeting someone. Terrible pain is often felt in the phantom limb.

Phantom limb sensation and the pain associated with it have been attributed to impulses entering the spinal cord from the scar of nervous tissue in the stump. In fact, removing the scar or cutting the sensory nerves just above it may relieve pain in some cases. But imaging studies of the somatosensory cortex of patients who have lost a hand suggest that phantom limb sensations are caused by a rearrangement of cortical circuits. As the afferents from the lost hand wither, adjacent afferent fibers expand into their place, just as in the monkeys with deafferented limbs.

In several patients the area of cortex that represented a hand before amputation now receives afferents from at least one other site on the skin. This has been called *remapping of referred sensations*. Stimuli applied to the face and upper arm are selectively capable of eliciting referred sensations in the phantom hand; both areas are represented in the brain next to the hand area (Figure 17–10). Thus changes in the arrangement of sensory afferents force changes in the readout of the

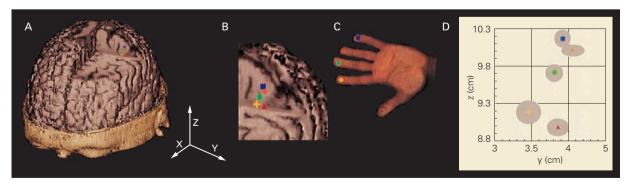

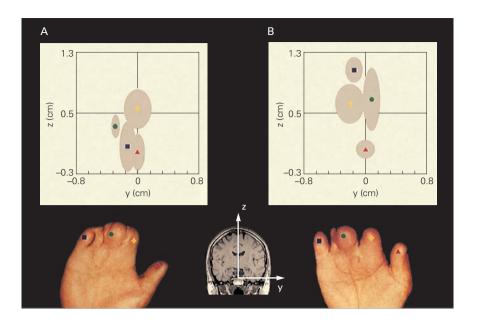

Figure 17–8 The representation of the hand in the somatosensory cortex can be visualized with magnetic encephalography. (Reproduced, with permission, from Mogilner et al. 1993.) A–C. The areas of representation of the fingers are indicated on a three-dimensional reconstruction of a subject's brain (color key is shown in C).

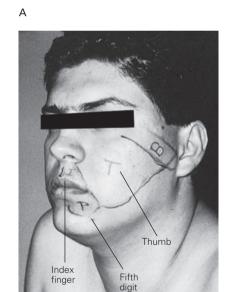

D. A two-dimensional plot of the cortex in the coronal phase shows discrete areas of representation for each finger. The data points are averages, the **gray ovals** indicate standard errors.

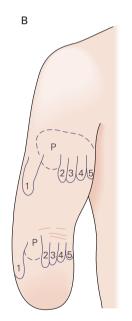

Figure 17–9 Cortical representation of the hand changes following surgical correction of syndactyly of digits 2 to 5. (Reproduced, with permission, from Mogilner et al. 1993.)

A. A preoperative map shows that the cortical representation of the thumb, index, middle, and little fingers is abnormal and lacks any somatotopic organization. For example, the distance between sites of representation of the thumb and little finger is significantly smaller than normal (see Figure 17–8D).

B. Twenty-six days after surgical separation of the digits, the organization of the inputs from the digits is somatotopic. The distance between the sites of representation of the thumb and little finger has increased to 1.06 cm.

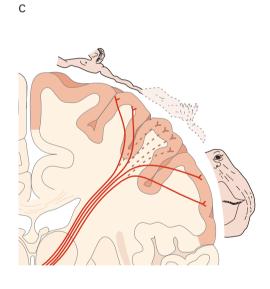

Figure 17–10 Phantom limb sensations can be evoked by stimulating particular areas of skin. Patients who have had an arm amputated experience sensation of the missing hand when their faces and upper arms are touched. (Reproduced, with permission, from Ramachandran 1993.)

A. The face of a patient whose arm was amputated above the left elbow is marked to show where stimulation (brushing the face with a cotton swab) elicits sensation referred to the phantom digits. Regions of the body that evoke referred sensations are called *reference fields*. Stimulation of the region labeled T always evokes sensations of the phantom thumb. Stimulation of facial areas marked I, P, and B evoke sensation of the phantom index finger, pinkie, and ball of the thumb, respectively. This patient was tested 4 weeks after amputation.

B. Another patient experienced referred sensation in two distinct areas on the arm—one area close to the line of amputation and a second area 6 cm above the elbow crease—in addition to sites on the face. Each area of referred sensation is a precise spatial map of the lost digits; the maps are almost identical except for the absence of fingertips in the upper map (P, palm). When the patient imagined pronating his phantom lower arm, the entire upper map shifted in the same direction by approximately 1.5 cm. Stimulating the skin region between these two maps did not elicit sensations of the phantom limb.

C. Portion of a sensory homunculus showing how the cortical area receiving inputs from the hand is flanked by the regions devoted to the face and the arm. Rearrangement of these cortical inputs is thought to be responsible for some types of phantom limb sensation.

sensory map—the brain learns to interpret activity on the patch of cortex receiving information from the face and upper arm as emanating from the amputated limb.

Extrapersonal Space Is Represented in the Posterior Parietal Association Cortex

Neurons in the primary somatosensory cortex areas 3a, 3b, and 1 project to higher-order unimodal areas of the anterior parietal lobe (Brodmann's area 2), and to multimodal association areas in the posterior parietal cortex (Brodmann's areas 5 and 7). The latter also receive input from the visual and auditory systems and from the hippocampus. The parietal association areas thus integrate somatic sensory information with other sensory modalities to form spatial percepts of objects in extrapersonal or far space.

Indeed, the connection between higher mental processes and specific nerve cells has been most dramatically demonstrated in these association areas in the posterior parietal cortex. Lesions here produce complex defects in personal or peripersonal spatial perception, visuomotor integration, and selective attention. Damage to the posterior parietal lobe produces object agnosia, a modality-specific inability to recognize certain kinds of objects even though afferent sensory pathways function normally. For example, some patients with posterior parietal damage are unable to recognize objects through touch (astereognosis). In fact, the most common agnosias result from lesions in the posterior parietal cortex.

Many patients with parietal lesions also show a striking deficit in awareness of one side of their body. For example, such patients may not dress, undress, or wash the affected side (*personal neglect syndrome*). They may even deny or disown their left arm or leg, going so far as to ask, "Who put this arm in bed with me?" Because the idea of having a left limb is foreign to them, patients may also deny the paralysis in this limb and attempt to leave the hospital prematurely because they feel nothing is wrong with them. Such denial about a disease or disability is referred to as *anosognosia*.

In some patients with right parietal lesions the sensory neglect extends from near space to far space. In these cases the ability to copy the left side of a drawing is severely disturbed. The patient may sketch the petals of a flower on the right side only. When asked to copy a clock, the patient may ignore the numbers on the left, try to cram all the numbers into the right half of the clock, or draw them on one side running off the clock face (Figure 17–11). A particularly dramatic example of spatial neglect is seen in self-portraits by

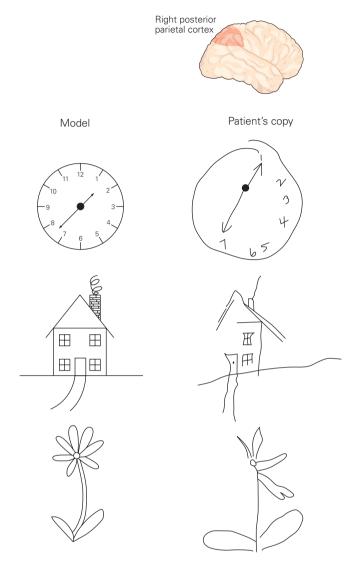

Figure 17–11 The drawings on the right were made by patients with unilateral visual neglect following lesion of the right posterior parietal cortex. (Reproduced, with permission, from Bloom and Lazerson 1988.)

a German artist who suffered a stroke that affected his right posterior parietal cortex. The portraits done in the two months after the stroke show a profound neglect of the left side of the face (Figure 17–12).

Spatial neglect can be quite selective. Some patients with neglect syndrome after injury to the right hemisphere have deficits in the perception of the form of objects. A patient may recognize an entire object but not all its parts, even though the visual pathways are intact (Figure 17–13).

Another form of spatial neglect is the neglect of one half of a remembered image, called *representational*

(lower right), by which time the artist had largely recovered. The early portraits show severe neglect of the left side of face, the side opposite the lesion. (Reproduced, with permission, from Jung 1974.)

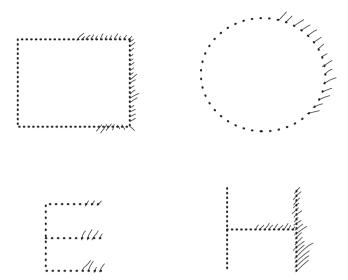

Figure 17–13 The neglect of space following injury to the right posterior parietal cortex is selective. Patients were shown drawings in which the shape of an object is drawn in dots (or other tiny forms) and then asked to mark with a pencil each dot. The figures here show the responses of one patient who neglected the left half of each object even though she was able to report accurately each shape (square, circle, letter E, letter H). (Adapted, with permission, from Marshall and Halligan 1995.)

neglect. This was first observed by the Italian neurologist Edoardo Bisiach in a group of patients in Milan, all of whom had injury to their right parietal lobe. Patients were asked to imagine that they were standing in the city's main public square, the Piazza del Duomo, facing the cathedral, and to describe from memory the buildings around the square (Figure 17–14). These subjects were able to identify all the buildings on the right side of the square (ipsilateral to the lesion) but could not recall the buildings on the left, even though these buildings were thoroughly familiar to them. The patients were then asked to imagine that they were standing on the steps of the cathedral, so that right and left were reversed. In this imagined position the patients were again asked to identify the buildings around the plaza. This time they identified only the buildings that they previously failed to name.

These results suggest that memory of external space is perceived in relation to the vantage point of the observer, not simply of that of objects in the environment. These Milanese patients clearly had stored a complete memory of the entire piazza and had complete access to that memory. But when they remembered the

piazza they neglected the left half, depending on the vantage point of the remembered image, because they were unable to recall images associated with their left side, contralateral to the side of the lesion. Thus, Bisiach concluded, memories for each half of the visual field are accessed through the contralateral hemisphere.

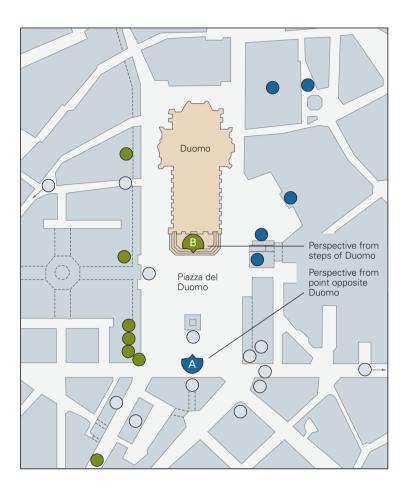

Recent PET studies indicate that when normal subjects close their eyes and imagine an object such as the letter "a," the visualization recruits activity in the primary visual cortex, just as when an actual object is seen with the eyes. Patients with representational neglect presumably lack such an orienting mechanism. Thus damage to the posterior parietal cortex, which impairs real-time visual perception, can also impair remembered or imagined visual images.

Much of Mental Processing Is Unconscious

In 1860 Herman Helmholtz, one of the pioneers in applying physical methods to perception, succeeded in measuring the conduction velocity of the nerve impulse to be approximately 90 m/s. He then went on to study reaction time—the time it took a subject to react to a stimulus-and found it to be much slower than the time required for the information to reach the brain by means of conduction time alone. This caused Helmholtz to realize that the brain must require a considerable amount of time to process sensory information before that information reaches conscious perception. Helmholtz proposed that this was the time the brain needed to evaluate, transform, and reroute the neural signals prior to our being aware of the significance of these signals. This unconscious inference, he argued, was required for perception and voluntary movement.

In the beginning of the 20th-century Sigmund Freud elaborated on Helmholtz's idea that much of mental activity is unconscious, pointing out that our unconscious mental life is not a single process but has at least three components: implicit, dynamic, and preconscious unconscious. Implicit unconscious is Helmholtz's unconscious inference. It includes, as we shall learn in Chapters 65 and 66, implicit memory, the type of memory that underlies learning perceptual and motor skills and which we now attribute to the striatum, the cerebellum, and the amygdala. The dynamic unconscious is that part of unconscious mental activity that involves our conflicts, repressed thoughts, and sexual as well as aggressive urges. This component of unconscious mental processes was the major focus of Freud's work. Finally, the preconscious unconscious is that part of the unconscious that is most readily accessible to consciousness. This component is

Figure 17–14 Milanese patients with lesions of the right posterior parietal cortex are able to recall only landmarks on their right in the Piazza del Duomo in Milan. Patients were asked to recall landmarks from memory from two points in the square. The blue circles in the map represent landmark buildings recalled from perspective A opposite the Duomo; the green circles represent landmark buildings recalled from perspective B on the steps of the Duomo. (Adapted, with permission, from Bisiach and Luzzatti 1978.)

concerned with organizing and planning for immediate actions, functions we now attribute to the prefrontal cortex.

The insight of Helmholtz and Freud that much of our mental life is unconscious raised the following related questions: What is left for freedom of action? What is the nature of free will? A major step in addressing this issue empirically was a study by Benjamin Libet. The study was based on an earlier finding that any voluntary movement is preceded by a readiness potential, a small electrical response recorded from the surface of the skull that occurs approximately one second before the movement. Libet asked subjects to will a movement and found to his surprise that a subject's awareness of his own willingness to move a finger followed, rather than preceded, the readiness potential and did so by as much as a full second. By recording neural activity we can predict a subject's desire to move a finger before the subject is aware of his own desire to move that finger! Thus what we consider acts of free will may have a significant unconscious step.

Is Consciousness Accessible to Neurobiological Analysis?

Consciousness Poses Fundamental Problems for a Biological Theory of Mind

Exploration of the nature of spatial neglect and free will touches on one of the great issues of cognitive neural science, and in fact of all science: the nature of consciousness. The unique character of consciousness has attracted fierce interest and debate among philosophers of mind because it is difficult to see how consciousness might be explained in reductionist physical terms.

At the beginning of this book we stated that what we commonly call *mind* is a set of operations carried out by the brain. Because consciousness is a fundamental property of mind, it too must be a function of the brain and in principle we should be able to identify neural circuits that give rise to it. However, before we can develop theories of consciousness that can be

tested by empirical science, we must first define consciousness in operational terms.

Here we should emphasize that, in general, the concepts that neuroscientists initially use to describe mental processes—such as learning, memory, or consciousness—are those developed by philosophers. Such concepts were formed without knowledge of how mental processes are mediated by the brain. Once neuroscientists define a specific mental process in psychological terms—and we can now do so quite precisely—they then can attempt to localize and analyze the neuronal systems that mediate the process. This approach, as we shall see, can now even be applied to consciousness.

Consciousness is ordinarily thought of as a state of self-awareness. Philosophers of mind such as John Searle and Thomas Nagel have defined three essential features of self-awareness: subjectivity, unity, and intentionality.

The subjectivity of self-awareness is the characteristic that poses the greatest philosophical and scientific challenge. Each of us has an awareness of a self that is the center of experience. Each of us experiences a world of sensations that feel unique and private. Our own experience seems much more real to us than the experiences of others. Our own ideas, moods, and sensations—our successes and disappointments, joys and pains—are experienced directly, whereas we can only indirectly appreciate other people's ideas, moods, and sensations. Is the aroma of lavender that I smell identical to your experience of lavender? This is not simply a question of our sensory capability. Even when sensory capabilities are measurably identical, the aroma of lavender is not only determined by the lavender but also by our personal history—the experience we recall from memory—and since experiential history is highly individualized, lavender may not produce the same subjective sensation in each of us.

Once we know how the aroma of lavender is mediated by neural signals that announce the presence of chemical molecules, how does our sensation, the conscious awareness of an aroma, arise from other neural networks of the brain?

The fact that conscious experience is fundamentally subjective raises the question of whether it is even possible to determine objectively some characteristics of consciousness that transcend individual experience. If the senses produce only subjective experience, the argument goes, those same senses cannot be the means of arriving at an objective understanding of experience.

The *unity* of self-awareness refers to the fact that our experience of the world at any given moment is felt as a single unified experience. All of the various sensory modalities are blended into a single experience. When we sit down to dinner we experience the chair against our back, the sound of music, and the fruity flavor of the wine as connected and simultaneous. When we speak to our dinner partners we do so in whole sentences; we are aware that we are completing an idea but pay little if any attention to the process of constructing sentences.

Finally, self-awareness has *intentionality*. That is, our conscious experience connects successive moments and we have the sense that successive moments are directed to some goal.

In earlier times these features of consciousness led some philosophers to a dualistic view of mind, a view that the body and the mind are very different substances—the body being physical and the mind existing in some nonphysical, spiritual medium. Today almost all philosophers of mind agree that what we call consciousness derives from physical properties of the brain. Thinkers about consciousness fall into two groups. The first group, of which Daniel Dennett is the most prominent advocate, thinks there is no problem of consciousness. Consciousness emerges quite simply from an understanding of neuronal activity. Dennett argues, much as did the neurologist John Hughlings Jackson a century earlier, that consciousness is not a discrete operation of the brain but the outcome of the computational activity of the association areas of the brain. The second group, which includes Francis Crick, Christof Koch, John Searle, Thomas Nagel, Antonio Damasio, and Gerald Edelman, believes that consciousness is a discrete phenomenon and that the issues of subjectivity, unity, and intentionality must be confronted if we are to understand how our experience is constructed.

Because consciousness has properties that other mental functions do not, a biological explanation poses a formidable problem, a problem so inherently difficult that the philosopher Colin McGinn has argued that consciousness is simply inaccessible to empirical study because of limitations inherent in human intelligence. Just as monkeys cannot understand quantum theory, humans cannot understand consciousness, McGinn argues. Conversely, Searle and Nagel argue that consciousness is accessible to analysis but we have been unable to explain it because it is a highly subjective and complex property of the brain unlike any function of the brain we understand—indeed, unlike any other subject of scientific inquiry.

Of the three features of consciousness, subjectivity is the most difficult to analyze empirically. Nagel and Searle illustrate the precise difficulty in the following way. Assume we succeed in studying a person's

consciousness by recording the electrical activity of neurons in a region known to be important for consciousness while that person carries out a particular task requiring conscious attention. How do we then analyze the results? Can we say that the firing of a group of neurons *causes* a private subjective experience? Does a burst of action potentials in the thalamus and somatic sensory cortex switch information into consciousness so that a person now perceives an object in his hand and perceives it as round or square, hard or malleable? What empirical grounds do we have for believing that when a mother looks at her infant child the firing of cells in the inferotemporal cortex concerned with face recognition causes conscious recognition of her child's face?

As yet we do not know even in the simplest case how the firing of specific neurons leads to conscious perception. In fact, Searle argues that we lack even an adequate theoretical model of how an ontologically objective phenomenon—electrical signals in another person's brain—can cause an ontologically subjective experience such as pain. Because consciousness is irreducibly subjective, it lies beyond the reach of science as we currently practice it.

Similarly, Nagel argues that because current science is essentially a reductionist approach to understanding phenomena it cannot address consciousness without a significant change in method, one in which the elements of subjective experience are defined. These elements are likely to be basic components of brain function much as atoms and molecules are basic components of matter. According to Nagel, object-to-object reductions are not problematic because we understand, at least in principle, how the properties of a given type of matter arise from the molecules of which it is made. What we lack are rules for extrapolating subjective experience from the physicochemical properties of interconnected nerve cells.

Nagel argues that our complete lack of insight into the elements of subjective experience should not prevent us from discovering rules that relate conscious phenomena to cellular processes in the brain. In fact, Nagel believes that the knowledge needed to think about a more fundamental type of analytical reduction from something subjective (experience) to something objective (physical)—can be gained only through the accumulation of cell-biological information. Only after we have developed a theory of mind that supports this novel and fundamental reduction will the limitations of the current reductionism become apparent. The discovery of the elementary components of subjective consciousness, Nagel argues, may require a revolution in biology and most likely a complete transformation of scientific thought.

Neurobiological Research on Cognitive Processes Does Not Depend on a Specific Theory of Consciousness

Most neural scientists whose work touches on the question of consciousness are not necessarily working toward or anticipating a revolution in scientific thought. Although neural scientists working on issues such as sensory perception and cognition must struggle with the difficulties of defining consciousness experimentally, these difficulties do not appear to preclude productive research. The physicist Steven Weinberg perhaps best expressed this attitude:

I don't see how anyone but George will ever know how it feels to be George. On the other hand, I can readily believe that at least in principle we will be able to explain all of George's behavior reductively, including what he says about what he feels, and that consciousness will be one of the emergent higher-level concepts appearing in this equation.

Indeed, neural science has made considerable progress in understanding the neurobiology of sensory perception without having to account for individual experience. Understanding the neural basis of perception of color and form, for example, does not depend on resolving the question of whether each of us sees the same blue. Despite the fact that perception of an object is constructed by the brain from piecemeal sensory information, and despite individual differences caused by experience, perception of an object is not arbitrary and appears to correspond to objective physical properties of the object. What we do not understand is the step from action potentials to awareness of an object.

Although the subjectivity of consciousness makes the neurobiological study of consciousness especially difficult, in principle such a study may not be insurmountable using current methods. The subjective nature of perception does not prevent one person from objectively studying what another person perceives. We have been able to correlate some regularities of perception with specific patterns of neuronal activity in different individuals under a variety of circumstances. The correlation between a neural event and a mental event, based on rigorous criteria, should be a sufficient first approximation of the neural process mediating a mental operation by any reasonable standards of scientific explanation. For this reason Crick and Koch emphasized that the first step in the analysis of consciousness is to find the neural correlates of consciousness, the minimal set of neural events that give rise to a conscious percept.

Finding the neural systems that mediate consciousness may not be simple. Gerald Edelman and

Stanislas Dehaene have argued that the neural correlates of consciousness are unlikely to be localized but rather widely distributed throughout the cerebral cortex and thalamus. There is extensive evidence of massive feedforward broadcasting as well as, feedback or recursive connections between cortical areas, which Dehaene believes may be essential for the conversion of unconscious to conscious perception.

By contrast, Crick and Koch believed that the most elementary neural correlates of consciousness are likely to involve only a small set of neurons, and therefore one should be able to determine the neural circuits to which they belong. Crick and Koch proposed a search for the neural activity that produces specific instances of consciousness, such as perception of the movement of an object, its shape, and its color. Having done that we may eventually be in a position to meet Searle's and Nagel's higher demands: to develop a theory of the correlations we discover empirically, to state the laws of correlation between neural phenomena and subjective experience.

Because at any moment we can be conscious of one of a large variety of sounds, smells, and objects as well as actions, consciousness must involve modulatory control over a variety of neural systems. Thus consciousness is required for many aspects of mental activity: visual perception, thinking, emotion, action, and the perception of self. Because we understand the visual system best, Crick and Koch argued that our efforts should be focused on visual perception and in particular on two phenomena: binocular rivalry and selective attention.

Studies of Binocular Rivalry Have Identified Circuits That May Switch Unconscious to Conscious Visual Perception

When two different images are presented simultaneously to the two eyes—horizontal bars to one eye, vertical bars to the other—the subject's perception alternates spontaneously from one monocular view to the other. Erik Lumer and his colleagues found in functional imaging experiments that whenever an individual switches from one eye to the next-from one conscious percept to the next—three sets of cortical areas are recruited. One is the ventral visual pathway of the temporal lobe, which is concerned with perceptions of objects and people. The others are the parietal and frontal regions, which are known to be involved in visual attention to space. Lumer and his colleagues suggest that the frontal and parietal areas are critical for conscious perception and that these areas focus awareness on specific internal representations of visual images.

Nikos Logothetis has carried out similar analyses at the level of individual neurons and confirmed that the competition between rivalrous stimuli in the two halves of the visual field is resolved late in the ventral pathway, in the inferior temporal cortex and the lower layers of the superior temporal sulcus. These regions in turn project to and receive connections from the prefrontal cortex. In light of these findings Crick and Koch argued that the pathways for conscious visual perception course through the inferior temporal cortex to the prefrontal and parietal cortices.

Selective Attention to Visual Stimuli Can Be Studied on the Cellular Level in Nonhuman Primates

Selective attention in vision is another useful starting point for a cell-biological approach to the study of consciousness. At any given moment we are aware of only a small fraction of the sensory stimuli that impinge on us. As we look out on the world, we focus on specific objects or scenes that have particular interest and exclude others.

If you raise your eyes from this book to look at a person entering the room, you are no longer attending to the words on this page. Nor are you attending to the decor of the room or other people in the room. This focusing of the sensory apparatus is an essential feature of all sensory processing, as Williams James first noted in his *Principles of Psychology* (1890):

Millions of items . . . are present to my senses which never properly enter my experience. Why? Because they have no interest for me. My experience is what I agree to attend to. . . . Everyone knows what attention is. It is the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects of trains of thought. Focalization, concentration of consciousness, are of its essence. It implies withdrawal from some things in order to deal effectively with others.

Cellular studies of the posterior parietal cortex in monkeys have provided important insight into the neural mechanisms of focusing attention on specific objects in the visual field. Like neurons in other visual processing centers, each parietal neuron fires when a visual stimulus enters its receptive field (see Chapter 25 for a description of the receptive fields of cortical neurons in the visual system). The strength of the neuron's response depends on whether the animal is paying attention to the stimulus. The response is moderate when the animal's gaze is directed away from the stimulus but vigorous when the monkey attends to the stimulus (Figure 17–15).

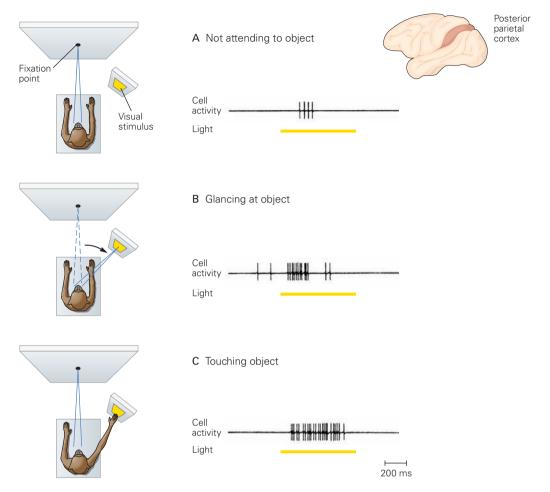

Figure 17–15 Neurons in the posterior parietal cortex of a monkey respond more vigorously to a stimulus when the animal is attentive to the stimulus. (Reproduced, with permission, from Wurtz, Goldberg, and Robinson 1982.)

A. A spot of light elicits only a few action potentials in a cell when the animal's gaze is directed away from the stimulus.

- B. The same cell's firing increases when the animal's eyes move to the stimulus.
- **C.** The cell's firing increases even more when the monkey touches the spot without moving his eyes.

These findings are consistent with the clinical observation that the parietal cortex is involved in focusing on objects in space. The response of the neuron is independent of how the animal attends to the stimulus. The firing rate of the neuron increases by about the same amount whether the animal merely looks at the stimulus or reaches for it while continuing to look elsewhere (Figure 17–15). This independence is significant because the posterior parietal cortex makes connections with structures in the prefrontal cortex that are involved in the planning and execution of movements of the eyes and hands.

When an object induces slightly disparate images in the two retinas, we do not see double images. Instead we perceive a single object in front of or behind the plane of fixation. Three-dimensional movies and Magic Eye books take advantage of this phenomenon, displaying slightly different images to each eye to induce a conscious perception of depth. Neurons in the primary visual cortex, the first synaptic relay of the visual system in the cerebral cortex, are sensitive to this retinal disparity and could therefore provide the basis for depth perception. However, these same neurons respond differently to black and white images that are anticorrelated and disparate—images in which each black pixel presented to one eye corresponds to a white pixel in the other, and vice versa. Although the neural synapse should give rise to a conscious perception of depth, in fact such images are not perceived as a single image having depth; instead they are treated as

rivalrous alternating images. One sees either a whiteon-black or black-on-white image, and the perceptual switch occurs spontaneously every few seconds, without any separation of depth.

Both retinal disparity and anticorrelated images produce an ocular reflex that adjusts the eyes to a depth of field equal to the plane of the image fixated, yet anticorrelated images are not perceived as one image with a single depth of field. The signal of depth triggers a cellular response in the primary visual cortex that is not consciously perceived and therefore does not have a direct role in conscious depth perception. It is thought that later stages of visual processing are responsible for depth perception and somehow reject the depth information computed for anticorrelated images in the primary visual cortex.

The study is important because it shows how neural activity can be dissociated from conscious perception. Disparate anticorrelated images are consciously perceived as rivalrous images—you see one input or the other but you do not see them fused into one object. However, neurons in the primary visual cortex do detect the anticorrelated images as fused and compute the depth of the fused image. In addition, the eyes make automatic vergence movements to the computed depth of the fused image that the brain does not consciously perceive.

These findings reinforce the idea that sensory input alone does not give rise to consciousness; higher-level interpretation of that input is needed.

How Is Self-Awareness Encoded in the Brain?

If visual attention is presently the most tractable example of consciousness, self-awareness is probably the deepest problem. Although aspects of self-awareness are evident in nonhuman primates, self-awareness is central to human identity and has evolved in parallel with language and other forms of symbolic communication.

A more promising approach to the study of consciousness may lie in the latest advances in neural prosthetics that give people the ability to voluntarily modulate neural signals to achieve a goal (move a cursor on the screen). Similarly, some individuals can achieve great control of their breathing and heart rate. These feats suggest that studies of how people can consciously control signals that are normally unconscious may shed light on the neural processes of self-awareness.

An Overall View

To come to grips with the biological processes of cognition, it is necessary to move beyond the individual neuron and consider how information is processed in neural networks. This requires not only the methods and approaches of cellular and systems neuroscience but also the insights of cognitive psychology.

The anterior regions of the parietal lobe contain elementary internal representations of the body surface and peripersonal space that can be modified by experience. Analysis of such modifications in the posterior parietal association cortex indicates that selective attention is a factor in integrating the internal representation of the body with perception of extrapersonal space. The representation of the body is integrated with the representation of actual, imagined, or remembered visual space, and self-consciousness functions within this integrated representation. Indeed, the Russian neuropsychologist A. R. Luria suggested that portions of the parietal lobe constitute the aspect of cortical organization that is the most distinctly human.

But it is likely that just as there is more than one form of spatial experience so there is more than one form of consciousness, each with different neural representations. Thus, Edelman and Damasio distinguish between primary (or core) consciousness and higher-order (extended) consciousness. Primary consciousness is an awareness of objects in the world, of the ability to form mental images of them. Primary consciousness is not unique to humans but shared by nonhuman primates and perhaps by other vertebrate animals as well. By contrast, higher-order consciousness involves a consciousness of being conscious and is uniquely human. It allows for a concept of past and future and therefore the ability to think of the consequences of one's acts and feelings.

In their attempt to develop a coherent reductionist approach to the study of consciousness, Crick and Koch began with Sigmund Freud's view that most mental functions are unconscious, including much of thinking. We are only conscious of the sensory representation of mental activities. Freud wrote in 1923: "It dawns upon us like a new discovery that only something which has once been a perception can become conscious, and that anything arising from within [apart from feelings] that seeks to become conscious must try to transform itself into external perception."

To study consciousness one must rely on first-person reports of (subjective) perception. Thus an empirical definition of consciousness must take into account behavioral output (action), which is integral not only to the study but also to our concept of consciousness.

Intuitively we think that a conscious percept is one we can describe in words. What are words? They are sounds we associate with sensory percepts based on a set of rules for manipulating those sounds (ie, language). Thus, we might consider conscious percepts

to be those percepts that can be flexibly linked with actions based on abstract rules.

If, while you are sleeping, a fly settles on your face and you wave it away, this action does not indicate consciousness. It is probably mediated by reflex pathways (similar to the pathways that mediate ocular convergence on rivalrous images). However, if asked to raise your right hand when sensing a light touch and your left hand when sensing a cold stimulus, you could perform that kind of action only if you were awake and conscious of the stimulus. Conscious percepts are those that can in principle support voluntary behavioral responses. This idea explains why correlates of consciousness show up in high-level areas that are also associated with action, such as parietal and prefrontal cortices.

The Organization of Cognition

Functionally Related Areas of Cortex Lie Close Together Sensory Information Is Processed in the Cortex in Serial Pathways

Parallel Pathways in Each Sensory Modality Lead to Dorsal and Ventral Association Areas

The Dorsal Visual Pathway Carries Spatial Information and Leads to Parietal Association Cortex

The Ventral Visual Pathway Processes Information About Form and Leads to Temporal Association Cortex

Goal-Directed Motor Behavior Is Controlled in the Frontal Lobe

Prefrontal Cortex Is Important for the Executive Control of Behavior

Dorsolateral Prefrontal Cortex Contributes to Cognitive Control of Behavior

Orbital-Ventromedial Prefrontal Cortex Contributes to Emotional Control of Behavior

Limbic Association Cortex Is a Gateway to the Hippocampal Memory System

An Overall View

In the previous chapter we examined how the activity of single nerve cells can be related to the internal representations required for simple cognitive tasks. In this chapter we survey the anatomical and physiological organization of the cortex through which the activity of populations of neurons mediate complex aspects of cognition. For this purpose we draw on the insights that have emerged from studies of the neural mechanisms of cognition in monkeys and studies of cognitive impairment resulting from brain

injury in humans. In the following chapter we extend this analysis to the premotor cortex and the control of voluntary movement. In Chapter 20 we discuss how neuroimaging studies of cognition in humans are consistent with the findings from these experimental and clinical studies.

Cognitive functions are mediated by specialized areas of neocortex distributed across the cerebral hemisphere in an orderly arrangement. This was already well established in 1962 when Alexander Luria published his landmark Higher Cortical Functions in Man. Neurologists of Luria's generation knew that lesions at neighboring sites on the cortical surface tend to produce related symptoms. For example, lesions of the occipital cortex give rise to lower-order visual deficits (cortical blindness), whereas lesions of adjacent temporal cortex result in higher-order visual deficits (object agnosia). Similarly, lesions in the posterior sector of the frontal lobe give rise to lower-order motor deficits (weakness and paralysis), whereas more anterior lesions give rise to higher-order deficits of executive control (the prefrontal syndrome). How can these observations be explained?

Luria proposed that sensory and motor cortex comprise multiple specialized subareas that are connected hierarchically. A primary sensory area lies next to a secondary sensory area that in turn borders a tertiary area. These areas have progressively more complex functions, culminating in the integration of multiple sensory modalities in the tertiary zones. Areas in the frontal lobe concerned with motor behavior are similarly organized. The primary motor cortex lies next to a secondary motor area (the premotor cortex) that in turn borders a tertiary area, the prefrontal cortex,

concerned with the executive control of behavior. In Luria's scheme sensory information flows into the central nervous system through a series of synaptic relays from primary to secondary to tertiary sensory areas, whereas motor commands flow from tertiary to secondary to primary motor areas. The tertiary areas at the peak of these sensory and motor hierarchies interact and are the seats of cognitive function.

More than 45 years after publication of Luria's book these general principles are still accepted. However, our understanding of the neural systems of cognition is far richer than that of Luria and his contemporaries, in large part because of newer methodologies.

Functionally Related Areas of Cortex Lie Close Together

The cortex of each cerebral hemisphere is a continuous sheet of gray matter. At the coarsest level, it consists of five lobes as illustrated in Figure 18–1. Within each of these lobes the cortex is further subdivided into anatomically and functionally defined areas.

Functional areas are distinguished by cellular structure, connectivity, and the physiological response properties of neurons. Identification of the functions of a cortical area requires characterizing the behavioral conditions under which its neurons are electrically active (by means of single-neuron recording) and determining its anatomical connections with other areas (by means of neuroanatomical tracers).

These invasive methods cannot be used in humans except under rare circumstances in which there is some clinical benefit. Consequently the major advances in identifying the function of anatomically or physiologically discrete areas of cortex have come from studies of animals, in particular the rhesus monkey, a species of the macaque (*Macaca*), an Old World monkey. Old World monkeys are our closest living relatives aside from the apes; like us, they are able to carry out demanding tasks that require well-developed cognitive abilities such as attention, memory, and pattern discrimination.

In the macaque a region of cortex is defined as functionally distinct if neurons within it have similar functional properties (such as responding to similar types of visual stimulation) and common connections (such as receiving the same input from primary visual cortex). In addition, to qualify as an area of lower-order sensory or motor cortex the neurons in that area must be organized into a single, coherent neural map of the sensory or motor periphery. The number of functionally distinct areas identified by these criteria

(Figure 18–1) is much greater than the number of areas defined cytoarchitecturally because an area with anatomically similar cells may contain several functionally and connectionally distinct areas.

A few simple precepts govern the organization of functional areas in the macaque cerebral cortex: (1) all areas fall into a few major functional categories; (2) areas in a given category occupy a discrete, continuous portion of the cortical sheet; and (3) areas that are functionally related occupy neighboring sites (Figure 18–2).

Sensory Information Is Processed in the Cortex in Serial Pathways

In analyzing how the areas of the cerebral cortex act together to produce behavior it is useful to ask, as in the study of social organizations, who talks to whom? Cortical areas communicate with each other by means of bundles of axons traveling together in identifiable tracts. As a result of neuro-anatomical tracing studies in the monkey, the neural tracts (or projections) running from area to area are now well understood. A dye injected into one population of neurons is carried by axonal transport to distant clusters of neurons that can be identified because they are labeled with the dye (see Box 4–2).

These tracing studies have confirmed Luria's idea that the sensory areas of cortex are organized hierarchically. Within each sensory system (visual, auditory, etc.) signals from the periphery arrive at a primary sensory area, such as the primary visual cortex (V1), primary auditory cortex (A1), or primary somatosensory cortex (S-I).

Primary sensory areas possess four properties characteristic of their role in the early stages of information processing.

- 1. Their input is from thalamic sensory relay nuclei. (The thalamus is the main subcortical source of input to all areas of cortex, but only some thalamic nuclei relay sensory signals).
- 2. The neurons in a primary sensory area have small receptive fields—the region on the receptor surface that must be stimulated in order for the neuron to fire—and are arranged to form a precise somatotopic map of the sensory receptor surface (retina, cochlea, or skin).
- 3. Injury to a part of the map causes a simple sensory loss confined to the corresponding part of the contralateral sensory receptor surface.
- 4. Connections to other cortical areas are limited, confined almost entirely to nearby areas that process information in the same modality.

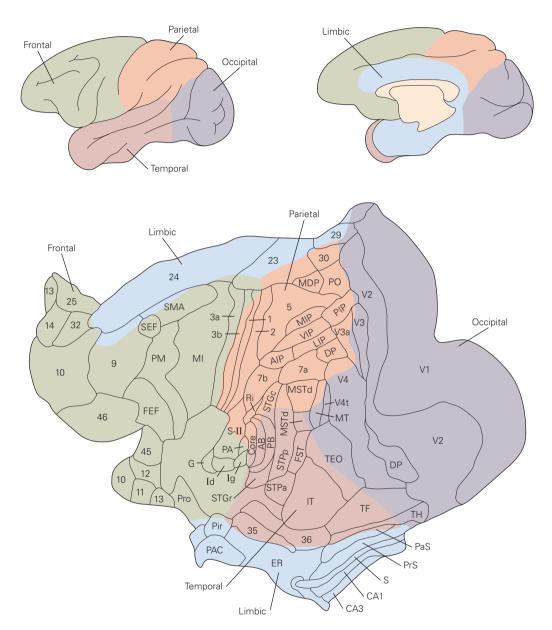

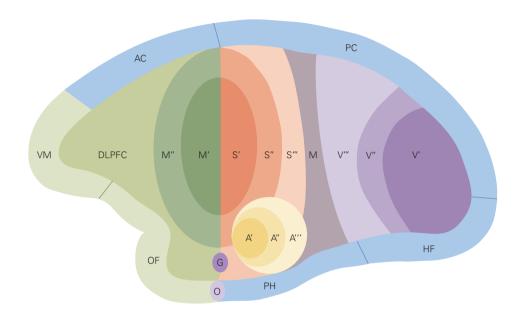

Figure 18–1 The cerebral cortex of the macaque monkey. Lateral and medial views show the location of five cortical lobes. The labeled areas on the unfolded hemisphere (lower panel) are those defined in physiological and anatomical studies. (Adapted, with permission, from Van Essen et al. 2001.)

The anatomical labels are as follows. The numbered areas are Brodmann's areas; AB, auditory belt; AIP, anterior intraparietal area; CA₁, CA₃, cornu ammonis fields of hippocampus; Core, primary auditory cortex; DP, dorsal prelunate area; ER, entorhinal cortex; FEF, frontal eye field; FST, floor of superior temporal sulcus; G, gustatory cortex; Id, Ig, insular cortex, dysgranular and granular divisions; IT, inferotemporal cortex; LIP, lateral intraparietal area; MDP, medial dorsal parietal area; M1, primary motor cortex; MIP, medial intraparietal area;

MSTd, MSTI, medial superior temporal sulcus, dorsal and lateral divisions; MT, middle temporal area; PA, postauditory area; PAC, periamygdaloid cortex; PaS, parasubiculum; PB, auditory parabelt cortex; PIP, posterior intraparietal; Pir, piriform cortex; PM, premotor cortex; PO, parieto-occipital area; Pro, orbital proisocortex; PrS, presubiculum; Ri, retroinsular area; S, subiculum; SEF, supplementary eye field; S-II, secondary somatosensory area; SMA, supplementary motor and adjacent cingulate motor areas; STGc, STGr, superior temporal gyrus, caudal and rostral divisions of auditory cortex; STPa, STPp, superior temporal polysensory area, anterior and posterior divisions; TEO, temporo-occipital area; TF, TH, parahippocampal areas; V_1 , V_2 , V_3 , V_{3a} , V_4 , V_{4tr} , visual areas; VIP, ventral intraparietal area.

Figure 18–2 The cerebral cortex is divided into discrete functional categories. Cortical areas in each functional category occupy a continuous physical region of the cortical sheet, shown here in a schematic version of the unfolded hemisphere in Figure 18–1. The table indicates the functionally distinct

areas within each category. Primary sensory areas send their outputs to multiple secondary sensory areas, which in turn provide inputs to tertiary (higher-order) areas. Multimodal areas are tertiary areas with significant input from more than one sensory system.

Higher-order sensory areas have a different set of properties that are important to their role in the later stages of information processing.

- 1. They receive little input from the sensory relay nuclei in the thalamus; instead, their input arises from other thalamic nuclei and lower-order areas of sensory cortex.
- 2. Their neurons have large receptive fields and are organized into imprecise maps of the array of receptors in the periphery.
- 3. Injury results in abnormalities of perception and of related cognitive functions but does not impair the ability to detect sensory stimuli.
- 4. They are connected not only to nearby unimodal sensory areas but also to distant areas in the frontal and limbic lobes.

Thus, sensory information is processed serially, with each area in the chain carrying out certain computations and conveying the results to the next area. For example, in the ventral pathway of the visual system, which is concerned with processing information about form, the pathway begins with neurons that respond to detailed features of a visual stimulus and proceeds to neurons that encode the overall form. Receptive fields of individual neurons in the primary visual cortex (V_1) span approximately 1 degree of visual angle; those of neurons in V₄ (a mid-order area) span approximately 10 degrees; and those in the inferotemporal cortex (a higher-order area) span up to 100 degrees. Thus an individual neuron in V₁ could be sensitive to a small detail in a face, such as an eyebrow aligned in a certain direction within its small receptive field, whereas a neuron in the inferotemporal cortex can respond to an entire face.

However, sensory pathways are not exclusively serial; in each functional pathway higher-order areas project back to the lower-order areas from which they receive input. In this way neurons in higher-order areas, sensitive to the global pattern of sensory input, can modulate the activity of neurons in lower-order areas that are sensitive to local detail. For example, top-down signals originating in the inferotemporal cortex might help neurons in V_1 to resolve a detail in a part of the face.

The hierarchical chain of sensory processing leads to areas with functions so complex that they cannot be described as simply sensory. In the late 19th century Santiago Ramón y Cajal proposed that areas with sensory functions were fundamentally distinct from those with cognitive functions, calling the latter the *association cortex*. This term is rooted in the

idea that cognition depends upon our learning which of the myriad stimuli impinging on our senses are associated with one another. Modern neuroscientists apply the term *association cortex* to regions of cortex where injury causes cognitive deficits that cannot be explained by impairment of sensory or motor function alone.

Large regions of association cortex are contained within each of the four lobes and contribute to cognition in distinctive ways.

The *parietal association cortex* is critical for sensory guidance of motor behavior and spatial awareness.

The *temporal association cortex* is important for recognition of sensory stimuli and for storage of semantic (factual) knowledge.

The *frontal association cortex* plays a key role in organizing behavior and in working memory.

The *limbic association cortex* serves complex functions related to emotion and episodic (autobiographical) memory.

Association areas have much more extensive input and output connections than do lower-order sensory and motor areas. Some association areas have a variety of visual, auditory, somatosensory, and motor connections that permit them to integrate sensory modalities or to use sensory information to guide motor behavior (see Chapter 19). In addition, all association areas are interconnected by a dense network of pathways within and between the parietal, temporal, frontal, and limbic lobes.

Parallel Pathways in Each Sensory Modality Lead to Dorsal and Ventral Association Areas

In addition to serial processing another principle of cortical organization is that the same information is processed differently in parallel pathways. In the visual system for example, two major parallel pathways terminate in different higher-order areas of cortex. The dorsal stream processes spatial information (position, motion, speed) and projects to parietal association cortex. The ventral stream processes information about form (color, shape, texture) and projects to temporal association cortex.

Dorsal and ventral pathways exist in other sensory systems as well (Figure 18–3). In the auditory and somatosensory systems dorsal pathways serve motor and spatial functions, whereas ventral pathways serve recognition functions. The dorsal-ventral division extends into frontal association cortex.

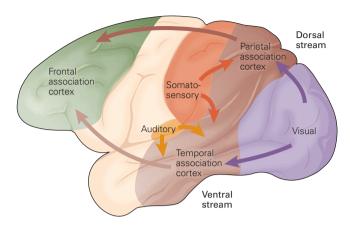

Figure 18–3 The dorsal and ventral systems of the cerebral cortex. Lower-order sensory areas send their output in parallel to the parietal (dorsal stream) and temporal (ventral stream) association cortices, which in turn send their output to the frontal association cortex. The parietal cortex projects primarily to dorsal areas of frontal cortex, areas that serve motor and executive control functions for which spatial information is important. The temporal cortex projects primarily to ventral regions of frontal cortex, including the orbital prefrontal cortex, areas that mediate emotional responses to things in the environment. Emotional significance can be assigned to an object only after the object has been recognized, an ability that depends on areas of the temporal lobe.

The Dorsal Visual Pathway Carries Spatial Information and Leads to Parietal Association Cortex

The parietal cortex plays a key role in the visual guidance of motor behavior and in spatial perception and cognition (and understanding where objects are relative to each other). These two functions are related because visuomotor control requires processing spatial information. Reaching for your coffee cup while you read the newspaper requires that the brain take into account where the image of the cup is on your retina and where your eyes are pointing so as to determine where the cup is relative to your hand.

The parietal cortex is ideally suited for such computations because it is connected to visual, somatosensory, and motor areas of cortex. Parietal cortex may have initially developed the capacity to represent where things are relative to the body to guide actions such as grasping, and then developed the ability to represent where things are relative to each other without reference to the body.

As we have learned in Chapter 17, injury to the parietal cortex in humans results in a wide range of behavioral impairments, which can be classified into two broad categories. In the first category are impairments of body awareness, motor control, and visual guidance of motor behavior. These deficits result from damage to dorsal parts of the parietal cortex close to and connected with the somatosensory cortex. In the second category are impairments of spatial perception and cognition. These deficits result from damage to ventral parts of parietal cortex close to and connected with the visual cortex. Thus the parietal cortex can be thought of as having two subdivisions: a dorsal component serving primarily motor functions and a ventral component serving primarily spatial functions.

Specific impairments in the first category include asomatognosia, a disorder of body awareness in which patients deny the existence of the arm or leg contralateral to the lesion or refuse to acknowledge that it belongs to them even when they can see it. Another is ideomotor apraxia, which arises from damage to the dominant hemisphere; patients are unable to execute certain movements such as waving goodbye, either on command or by imitation, although they may spontaneously make the same movement under circumstances that evoke it habitually. A third deficit in this category, optic ataxia, results from damage to the dorsomedial parietal cortex. Patients with this deficit have difficulty reaching for an object in the peripheral visual field (as when reaching for a coffee cup while reading the newspaper). The hand may go to the wrong location, or it may be misoriented when attempting to grasp the object (Figure 18-4). Patients can, however, perform a reaching task that does not depend on vision, for example touching one's knee in the dark, and can report the locations of visible objects correctly. This collection of symptoms cannot be explained by a purely motor or purely visual mechanism but instead reflects difficulty in coordinating visual input and motor output.

Specific impairments in the second category include hemispatial neglect. Patients with this defect are profoundly inattentive to events in the half of space opposite the injured side (see Chapter 17). Another is constructional apraxia, an inability to appreciate the structure and arrangement of things by looking at them. Patients suffering from constructional apraxia have difficulty arranging a set of tiles or matchsticks according to a model placed in plain view. They may also be deficient in tests of writing and drawing because these require putting marks on a page in a precise arrangement (Figure 18–5).

Injury to parietal cortex can impair cognitive tasks that require abstract spatial thinking. For example, patients with acalculia have trouble understanding and manipulating numbers, particularly multidigit numbers where the value of a digit depends on its place.

Inaccurate preshaping of grasp

Normal Impaired

Misdirected reach

Misorientation of hand

Figure 18–4 Patients with damage to the dorsomedial parietal cortex have difficulty with visually guided grasping and reaching (optic ataxia). When required to grasp an object, patients fail to shape their hand appropriately. When required to place their fingers through a slot in a plate, they reach to the wrong location and fail to orient the hand correctly. (Adapted, with permission, from Jeannerod 1986 [left panels]; and Perenin and Vighetto 1988 [right panels].)

Injury to the left angular gyrus, a region at the lateral edge of the parietal lobe, results in agraphia with alexia, a condition in which patients cannot read, write, or spell and cannot understand a word spelled out orally. Reading and writing involve spatial thinking in that they depend on the ability to perceive, remember, and reproduce the sequence of letters in a word.

Although clinical observations pinpoint the parietal cortex as important for many spatially based abilities, they do not tell us about the underlying neural mechanisms. Our understanding of these mechanisms comes in large part from studies of monkeys using single-neuron recording. Four areas in the monkey's intraparietal sulcus have been thoroughly studied: the lateral, ventral, medial, and anterior intraparietal areas. Neurons in all of these areas carry spatial information, signaling the location of an object to which the monkey is paying attention or is about to direct movement. Within a given area neurons respond to one or more specific kinds of sensory stimulation (somatosensory or visual), fire in conjunction with a specific kind of movement (looking, reaching, or grasping), and encode the location of a target relative to a specific part of the body (eye, head, or hand) or the environment.

The lateral intraparietal area encodes retinacentered information about points in the visual field that the monkey has selected for attention and is involved in visual attention and eye movements. Its neurons, like those in unimodal visual areas, have receptive fields for fixed points on the retina. Visual responses in these neurons increase when the monkey is paying attention to a stimulus in the receptive field (Figure 18–6A). This enhancement of the response occurs whether or not the monkey is planning an eye movement toward the stimulus. Neurons here also fire when the monkey is anticipating the appearance of a stimulus or remembering the location where a stimulus appeared, and some neurons fire around the time of an eye movement toward the receptive field.

The ventral intraparietal area encodes head-centered spatial information about visual and tactile stimuli and is involved in multisensory guidance of head and mouth movements. Individual neurons respond to both visual and somatosensory stimuli. Most neurons respond to tactile stimulation on the face or head and to visual stimuli presented near the receptive field. The match between somatosensory and visual receptive fields is maintained when the eyes move: The visual receptive fields are shifted so as to remain at a fixed position relative to the head (Figure 18–6B).

The medial intraparietal area encodes both retinacentered and body-centered spatial information and is involved with visually guided reaching. Neurons in this area respond to visual targets and are active when the monkey is planning and executing reaching movements. They are sensitive to the direction of reaching

in relation both to where the monkey is looking (right or left of the gaze) and to the body (right or left of the trunk) (Figure 18–6C).

The anterior intraparietal area encodes object-centered and hand-centered spatial information and is involved with visually guided grasping. Individual neurons are selective for objects of particular shapes and for the hand shapes required to grasp them. A neuron that fires when the monkey sees a given object will also fire when it prepares to grasp that object (Figure 18–6D).

Clinical observations in humans and electrophysiological studies in monkeys lead to two general conclusions. First, the parietal cortex is specialized for the sensory guidance of motor behavior as well as for spatial perception and cognition. Second, different regions within the parietal cortex serve different functions: Dorsal regions close to the somatosensory cortex contribute to motor control of the body, whereas ventral regions close to the visual cortex contribute to spatial perception and cognition.

The Ventral Visual Pathway Processes Information About Form and Leads to Temporal Association Cortex

The temporal association cortex, like the parietal association cortex, is a region where higher-order areas of different sensory systems share borders and are interconnected. These association areas receive information about vision, sound, and touch from lower-order

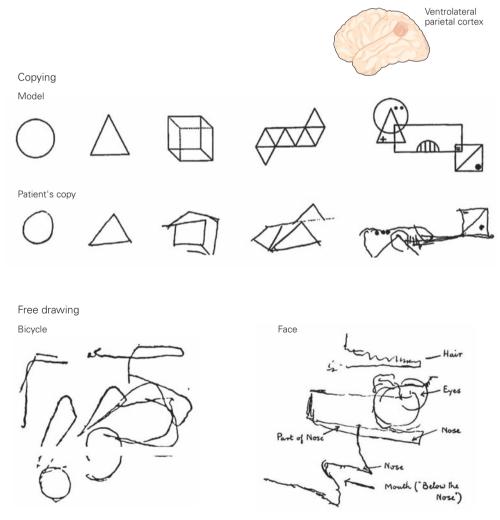

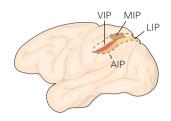

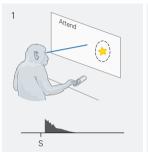

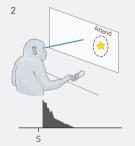

Figure 18–5 Disorders of copying and drawing result from damage to the parietal cortex. Drawings of complex figures are grossly inaccurate whether drawn from a model or from

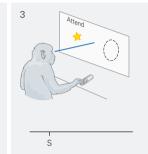

memory. The problem arises from an inability to perceive the spatial relations of the parts of an object. (Reproduced, with permission, from Critchley 1953; and Trojano and Grossi 1998.)

B Ventral intraparietal area

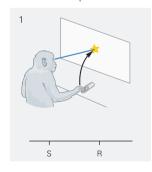

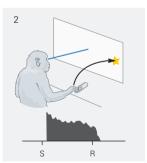

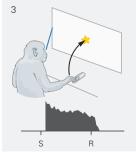

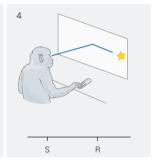

Head-centered

C Medial intraparietal area

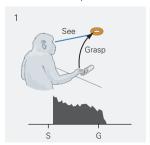

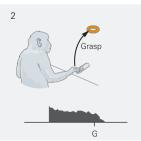

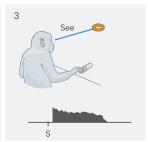

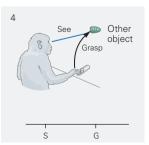

Retina-centered direction of reach; preparation to reach

D Anterior intraparietal area

Retina-centered, object-specific viewing, grasping visual, auditory, and somatosensory areas. For example, the inferotemporal cortex receives information about the shape, color, and texture of visual images through the ventral visual pathway. The temporal association cortex uses this information to mediate the recognition of objects in the environment and, through projections to the ventral frontal cortex, trigger appropriate emotional responses to them (see Figure 18–3).

Injury to the visual and auditory association areas of the temporal lobe in humans impairs recognition of the significance of sensory stimuli, resulting in a variety of perceptual deficits termed *agnosias*. Patients with visual object agnosia, a result of injury to a medioventral part of the temporal cortex, cannot recognize things but can draw them (Figure 18–7). This deficit is a striking contrast to patients with parietal cortex injury, who can recognize things but often cannot draw them well (Figure 18–5). Patients with visual object agnosia may be unable to recognize objects in general or may be unable to make fine distinctions within a category of objects such as faces. An impairment in recognition specific to faces is called prosopagnosia.

Auditory agnosia has been described, although reports of it are rare, perhaps because the condition is associated with more disabling disorders of language comprehension. Patients with auditory agnosia, when asked to describe recordings of natural sounds, demonstrate that they are not deaf but that their ability to recognize the sounds is impaired.

Figure 18–6 (Opposite) Neurons in the parietal cortex of the monkey are selective for the location of objects in the visual field relative to particular parts of the body. Each histogram represents the firing rate of a representative neuron as a function of time following presentation of a stimulus. In each diagram the line emanating from the eyes indicates where the monkey is looking.

A. Neurons in the lateral intraparietal area (LIP) have retinacentered receptive fields. The strength of the visual response depends on whether the monkey is paying attention to the stimulus. The neuron fires when a light is flashed inside its receptive field (dotted circle) (1). The visual response is increased if the monkey is instructed to attend to the location of the stimulus (2). The neuron does not fire if the stimulus is presented outside the receptive field regardless of where attention is directed (3, 4).

B. In the ventral intraparietal area (VIP) some neurons have head-centered receptive fields. This is determined by keeping the head in a fixed position while the monkey is instructed to shift its gaze to various locations. This neuron fires when a light appears to the right of the midline of the head (1, 2). It does not fire when the light appears at another location relative to the

By far the most debilitating of all conditions arising from damage to the human temporal lobe is Wernicke aphasia, a disorder in understanding spoken language. Wernicke aphasia arises from damage to the superior temporal gyrus of the left hemisphere, a region corresponding to Brodmann's area 22 (comparable in location to the auditory association cortex in the superior temporal gyrus in the monkey). In addition to the disorder of speech comprehension, the patient's own speech is severely garbled. This indicates that auditory forms of words stored in the temporal lobe serve not only as templates for speech recognition but also as guides for speech production.

Semantic dementia is a degenerative disorder typically arising from pathology of the temporal cortex. Studies of patients with this disorder indicate that this part of cortex is critical not only for object recognition but also for semantic memory. To have semantic knowledge of a thing means that one must be able to associate disparate pieces of information about it, for example, the sound, feel, appearance, and use of a telephone. These associations are forged through experience-dependent changes in the synaptic connections among the same temporal lobe areas on which recognition depends. A patient with semantic dementia shown pictures of an ostrich and a penguin may name them simply "bird" or even "animal." The loss of detailed knowledge about things in the world emerges even in tests requiring only nonverbal responses, such as placing together pictures of things that are semantically related.

head, as on the midline or to the left (3, 4). The critical contrast is between situations 1 and 4. The retinal location of the light is the same in both (slightly to the right of the fixation point) yet the neuron fires in 1, when the stimulus is to the right of the head, but not in 4, when the stimulus is to the left of the head.

C. In the medial intraparietal area (MIP) neurons fire when the monkey is preparing to reach for a visual target and are selective for the retina-centered direction of the reach. This neuron fires when the monkey reaches for a target to the right of where he is looking (2, 3). It does not fire when he reaches for a target at which he is looking (1) or when he moves only his eyes to the target at the right (4). The physical direction of the reach is not a factor in the neuron's firing: It is the same in 1 and 3 and yet the neuron fires only in 3.

D. In the anterior intraparietal area (AIP) neurons fire when the monkey is looking at or preparing to grasp an object and are selective for objects of particular shapes. This neuron fires when the monkey is viewing a ring (3) or making a memory-guided reach to it in the dark (2). It fires especially strongly when the monkey is grasping the ring under visual guidance (1). It does not fire during viewing or grasping of other objects (4).

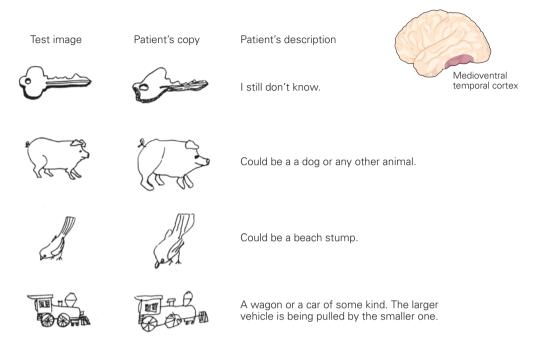

Figure 18–7 Injury to a medioventral region of temporal cortex results in visual object agnosia. When presented with the drawings shown in the left column, a patient with visual

object agnosia was able to copy them but could not accurately identify the objects. (Reproduced, with permission, from Rubens and Benson 1971.)

Neurons in the temporal association cortex of monkeys become active under circumstances that suggest involvement in object recognition. The best understood area of temporal association cortex is the inferotemporal cortex, which occupies most of the inferior temporal gyrus and extends dorsally into the superior temporal sulcus. The activity of inferotemporal neurons, unlike neurons in the parietal cortex, is not influenced by the motor behavior of the animal. If a visual stimulus enters the neuron's receptive field and the monkey is paying attention to it, the neuron will fire at a virtually identical rate regardless of what the animal is doing or planning to do.

Inferotemporal neurons also differ from parietal neurons in that they are sensitive to the shape, color, and texture of an object in the visual receptive field. In one study individual inferotemporal neurons responded to only a few shapes out of a large test set (Figure 18–8). Because each neuron responded to different stimuli, it was possible by monitoring the activity of many neurons to determine reliably which stimulus was present on the screen. The pattern selectivity of inferotemporal neurons is largely unaffected by image size and location as long as the image falls somewhere in the neuron's typically large receptive field. This insensitivity to size and location is further evidence that the inferotemporal

cortex plays a role in shape recognition (for which location and size are irrelevant) but not in motor guidance (for which they are crucial).

Just as neurons in the inferotemporal cortex are selective for visual shapes, neurons in the auditory association cortex of the superior temporal gyrus are selective for patterns of sound. Although little studied, this region is known to contain neurons selective for particular species-specific vocalizations. Overall, the temporal association cortex plays a critical role in recognizing things and in storing some kinds of knowledge. It is not involved in the guidance of movement or in spatial perception and cognition, functions that depend instead on parietal cortex.

Goal-Directed Motor Behavior Is Controlled in the Frontal Lobe

All areas of the frontal lobe participate in the control of motor behavior but in different ways. Just as in the posterior sensory cortex, frontal areas are connected in series in a functional hierarchy (Figure 18–9). At the lower end of the chain is the primary motor cortex (Brodmann's area 4), also referred to as M1. Neurons here are organized into a detailed map of the body.

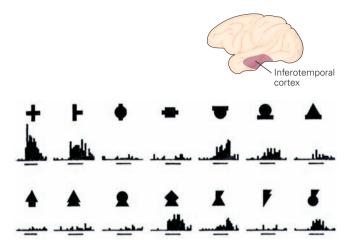

Figure 18–8 Neurons in the inferotemporal cortex of the monkey respond selectively to particular shapes. Shown are responses of a single inferotemporal neuron to 14 different silhouette shapes. The histogram under each shape represents the rate at which the neuron fired as a function of time during a 2-second trial. The bar under the histogram indicates the 1-second period during which the stimulus appeared. (Reproduced, with permission, from Kobatake et al. 1998.)

The primary motor cortex has numerous subregions that produce movement of different parts of the body.

Adjacent to the primary motor cortex and reciprocally connected to it are several higher-order motor areas collectively called the premotor cortex. Neurons in each of these areas are arranged in a comparatively coarse map of the body. Neuronal activity in the premotor areas reflects global aspects of motor behavior such as the combination of limbs to be used or the sequence of movements. In addition, the premotor cortex of the inferior frontal gyrus contains mirror neurons that respond to the movement of others (see Chapter 19). The premotor cortex is connected to the dorsolateral prefrontal cortex, which is important for cognitive control of motor behavior. This area is connected in turn to the orbital-ventromedial prefrontal cortex, an area involved in emotional processes associated with the executive control of behavior.

In contrast to the sensory systems, where information flows from the periphery into higher-order areas, in the motor systems signals flow from the higher-order areas of the frontal lobe to the primary motor cortex. Emotional processes in the orbital-ventromedial prefrontal cortex influence cognitive processes in the dorsolateral prefrontal cortex, which in turn act on spinal motor nerves through the premotor and primary motor cortex.

Prefrontal Cortex Is Important for the Executive Control of Behavior

Much of what we do in daily life depends on our ability to remember and act on intentions. Intentions can be simple or nested; they can concern particular actions or general plans, a small bit of mental arithmetic or a career path. The mental processes underlying the executive control of behavior are so diverse that it seems unlikely that they could be served by one area of the brain. Yet, remarkably, a single large region of the cerebral hemisphere, the prefrontal cortex, is implicated in many forms of executive control.

Patients with damage confined to the prefrontal cortex are typically normal in their perceptual ability and motor behavior and may perform normally on tests of intelligence. Yet they are unable to function effectively in daily life. Their emotional state is abnormal, and their behavior is disorganized because they lack concentration and thus are ineffective at carrying out plans. The physician John Harlow, writing in 1868, provided the first clear description of such a case. His patient, Phineas Gage, was a railroad worker who had suffered extensive prefrontal damage when blasting powder, exploding prematurely, drove a tamping iron through his head (Figure 18-10). Formerly "a shrewd, smart business man, very energetic and persistent in pursuing all his plans," Gage seemed transformed into another person altogether, "pertinaciously obstinate, yet capricious and vacillating, devising many plans of future operation, which are no sooner arranged than they are abandoned in turn for others appearing more feasible."

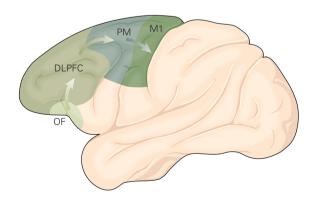

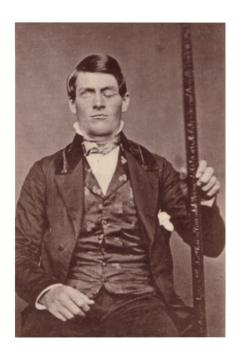

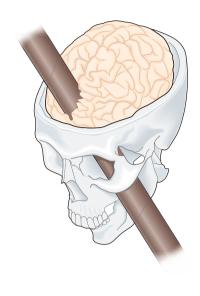

Figure 18–9 Regions of the frontal lobe are connected in series. Emotional and cognitive processes in the prefrontal cortex exert control over behavior through a pathway that begins in the orbitofrontal-ventromedial prefrontal cortex (**OF**) and from there projects to the dorsolateral prefrontal cortex (**DLPFC**), the premotor cortex (**PM**), and finally the primary motor cortex (**M1**).

Figure 18–10 A 19th century case revealing the dependence of personality on prefrontal cortex.

Left: Phineas Gage with the 3-foot long tamping iron that was driven through his head by an explosion. (Adapted and reproduced, with permission, from the collection of Phyllis Gage Hartley.)

Right: A computer reconstruction of a drawing of the passage of the tamping iron through Gage's brain. This injury resulted in severe personality changes that added to our understanding of the function of the frontal lobes. (Adapted, with permission, from H. Damasio et al. 1994.)

Patients with prefrontal damage are unable to travel on their own because they will board whatever bus comes along first. They are unable to wait on tables in a restaurant because they lack the ability to respond to competing demands. One patient, an accomplished cook before sustaining brain damage, was able to use familiar recipes but could not follow new ones. If she went out to buy food she might be gone for hours, having coffee with a friend and forgetting all about the task at hand.

Emotional tone following prefrontal injury typically is characterized by flatness, shallowness, and indifference. This may take the form of loss of religious feeling, loss of appreciation for literature or music, insensitivity to the feelings of others, or indifference to the financial consequences of one's own actions.

Similar emotional changes occur in nonhuman primates. The observation by Charles Jacobsen that chimpanzees with prefrontal lesions no longer became upset when they failed to perform simple tasks led the Portuguese neurosurgeon Egas Moniz to introduce prefrontal lobotomy as a last-resort treatment for uncontrollable behavioral problems in patients with mental illness. This treatment was ultimately abandoned because of its devastating and irreversible damage to the patient's personality. Although cognitive and affective problems often occur together, cognitive deficits are especially pronounced after injury to dorsolateral prefrontal cortex, whereas emotional abnormalities are especially pronounced after orbital-ventromedial injury.

Dorsolateral Prefrontal Cortex Contributes to Cognitive Control of Behavior

Injury to the dorsolateral prefrontal cortex results in cognitive deficits that are manifested in a number of objective tests ranging from the very complex to the remarkably simple. An example of a complex test is to send patients on a shopping expedition with a set of specific instructions on where to go and what to buy. Typically, patients do not comply with the instructions, break accepted rules of social interaction, proceed inefficiently, and consequently fail to obtain all of the items specified.

A simple test that is highly sensitive to dorsolateral prefrontal damage is the Wisconsin Card Sort Test. Subjects are given a deck of cards printed with symbols and must select one card at a time and place it next to one of four samples. Told only whether each choice is correct or incorrect, they must discover by trial and error whether the correct choice is based on the number of symbols on the card, their shape, or their color (Figure 18-11). Patients with lesions of the dorsolateral prefrontal cortex persist in using an unsuccessful strategy, making so-called perseverative errors. They also make capricious errors, abandoning a successful rule unnecessarily. It is as if conscious oversight of behavior has been weakened, releasing habitual or random responses that are normally suppressed. It is easy to see how this condition could give rise to erratic behavior in everyday tasks.

Tests of verbal fluency are also sensitive indicators of dorsolateral prefrontal injury. When instructed to write down as many five-letter words as possible beginning with the letter "R" within a limited period of time, patients with prefrontal lesions produce relatively few words and sometimes break the rule by generating words with fewer or more letters than the required number. Asked about what it is like to perform this task, one patient said: "My brain becomes a blank. I completely run out of words. I can't think any more."

Studies of nonhuman primates have helped us understand the functions of the prefrontal cortex. Systematic study of prefrontal contributions to cognition began with Jacobsen's demonstration in the 1930s that chimpanzees with prefrontal lesions do poorly in delayed-response tasks. In a typical delayed-response task the animal is allowed to watch while

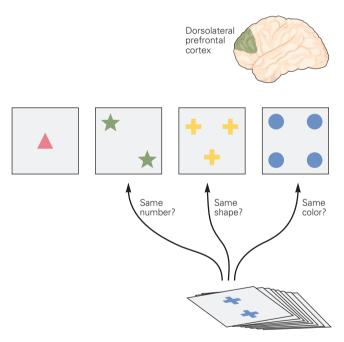

Figure 18–11 The Wisconsin Card SortTest evaluates cognitive deficits resulting from damage to dorsolateral prefrontal cortex. The patient selects one card at a time from the deck, places it next to one of the samples, and is told whether the choice was correct or incorrect. The patient must determine by trial-and-error whether the correct strategy is to place the card next to the sample with symbols of the same number (here two), the same shape (here crosses), or the same color (here blue). The rule according to which the tester announces choices to be correct or incorrect changes intermittently and without warning. Healthy subjects rapidly adjust their strategy, but patients with prefrontal damage typically continue to use the old strategy long after it has ceased to be effective. (Reproduced, with permission, from Milner and Petrides 1984.)

food is placed under one of two objects and a curtain is drawn. After a delay the curtain is raised, and the animal is allowed to lift one of the two objects. If the animal chooses the object covering the piece of food, it is allowed to retrieve and eat the food. The success rate is lower in animals with prefrontal lesions than in normal controls, especially with long delays. Later studies in macaque monkeys showed that this deficit results specifically from injury to the dorsolateral prefrontal cortex in and around the principal sulcus, roughly coincident with Brodmann's area 46.

Single-cell recordings in the prefrontal cortex of monkeys have cast light on why neuronal activity here is important to delayed-response performance. The ocular delayed-response task has been widely used in such investigations. Early in each trial, while the monkey is looking at a spot projected in the center of a screen, an image flashes briefly in the periphery of the screen. After the peripheral image has been extinguished the monkey must continue to fixate the central spot until it goes off, which is the instruction to look to the peripheral location where the image had appeared. During the delay period some neurons in the dorsolateral prefrontal cortex are active; these neurons are selective for specific locations. For example, a neuron may fire strongly when the monkey is planning to move to the left but only weakly when movement to the right is planned. This neuronal activity during the delay between a stimulus and the response maintains information on the location of the stimulus after it has vanished.

Is such activity in the prefrontal cortex related specifically to planning movements or to a more general function such as working memory? (Working memory is the ability to hold information in mind and manipulate it mentally, as when dialing a telephone number or doing mental arithmetic.) To answer this question, researchers carried out single-cell recordings in monkeys that had to remember information without planning a specific movement. Under these conditions some prefrontal neurons were active (Figure 18–12), indicating that prefrontal cortex is not concerned exclusively with planning movement. Nevertheless, working memory and executive control of movement may be related because both depend on the ability to retain information over time. Presumably a patient who is sent to buy food but ends up going off with a friend is unable to hold in her mind the plan with which she set out.

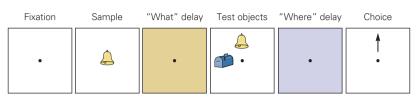

Orbital-Ventromedial Prefrontal Cortex Contributes to Emotional Control of Behavior

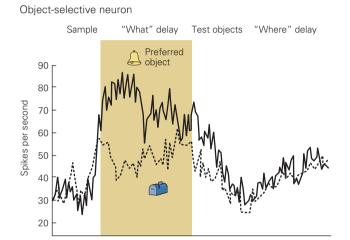

The orbital-ventromedial prefrontal cortex plays a critical role in goal-directed behavior because of its

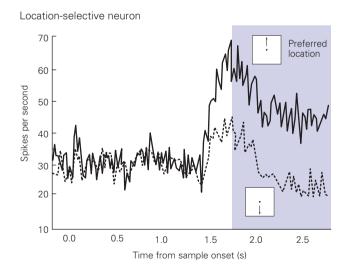

Figure 18-12 Neurons in the dorsolateral prefrontal cortex of a monkey are involved in holding information in working memory. In the experiment illustrated here a trial begins with the monkey looking at a small spot in the center of the screen. Then a sample object (in this case a bell) appears briefly. The screen is then left blank for a period during which the monkey has to fixate a central spot and remember what object was presented (the "what" delay). Two test objects are then displayed at different locations on the screen (in this case the bell at the screen's top and a mailbox at the screen's left). The monkey has to recognize the object matching the previous sample (the bell) and note its location (at the top of the screen). The display then vanishes and a second delay period ensues during which the monkey has to fixate the spot in the screen center and remember where the matching object was presented (the "where" delay). At the end of the delay four dots are displayed in the periphery and the fixation spot is extinguished. To complete the trial successfully the monkey has to make an eye movement to the dot at the location where the matching object appeared (the top of the screen in this example).

The firing rate of two neurons is shown as a function of time during the trial. During the "what" delay (requiring the monkey to remember what image had been presented) a typical object-selective prefrontal neuron was more active when the monkey was correctly remembering a bell rather than choosing the alternative object (in this trial a mailbox). During the "where" delay (requiring the monkey to remember where to make an eye movement) a typical location-sensitive neuron was more active when the monkey was preparing to shift his gaze upward than downward. connections to three neural systems. (1) It is linked strongly to the hypothalamus and amygdala, subcortical structures that mediate homeostatic drive states such as hunger and thirst and instinctual drive states such as those that underlie fear, aggression, and mating. Through these connections it has access to information about various drives. (2) It receives input from

every sensory system including the gustatory and olfactory systems. Through these inputs it has access to information about objects such as their color, texture, and taste that allow recognition and appropriate emotional responses. (3) It projects to the dorsolateral prefrontal cortex, which in turn projects to premotor cortex. Through this pathway it is in a position to

trigger appropriate behavior. For example, if hunger were strong and a nearby fruit had the color, texture, and taste of ripeness, then the orbital-ventromedial prefrontal cortex could trigger eating.

In some patients with injury to the orbital-ventromedial prefrontal cortex the emotional control of behavior is severely affected, although cognitive impairments are relatively minor. One such patient, EVR, performed at normal or above normal levels on numerous tests of cognitive ability, including the Wisconsin Card Sort Test. Yet in day-to-day life he was incapacitated in part by impaired decision making. His indecisiveness in selecting a restaurant exemplifies the problems that beset him. It could take him hours to

choose a restaurant as he drove to each one and carefully considered the relative merits of the menu, seating plan, and atmosphere.

Patients like EVR fail in clinical tests of decision making as well. In the Gambling Task the participant selects at will one card at a time from any of four decks. With some selections the subject receives a reward, with others a penalty is imposed. The schedule of rewards and penalties is such that decks A and B deliver larger individual rewards but lower net returns. Healthy subjects learn by trial and error to avoid these bad decks and to select from decks C and D instead. EVR showed the opposite pattern, persisting in a losing strategy (Figure 18–13). Presumably he did so because he lacked

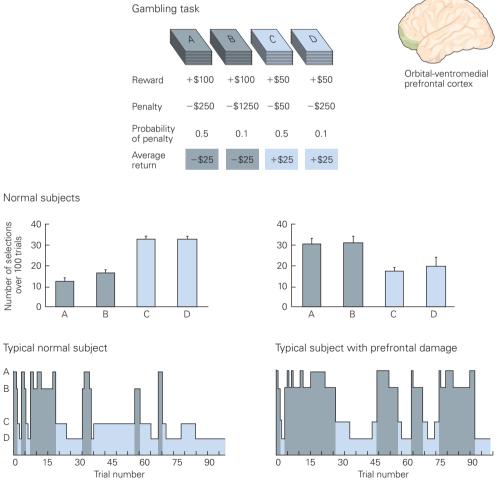

Figure 18–13 Injury to the orbital-ventromedial prefrontal cortex impairs anticipation of the consequences of decisions. This impairment is evident in a gambling task. Choosing cards from two stacks (A and B) leads to a net loss, whereas choosing from the other two (C and D) leads to a net gain.

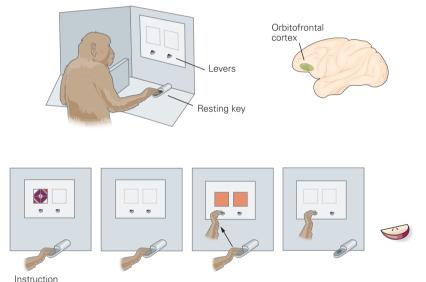

Healthy subjects learn by trial and error to make the majority of their choices from stacks C and D. Patients with damage to the orbital-ventromedial prefrontal cortex do not adjust their strategy over time to maximize the reward. (Reproduced, with permission, from Bechara et al. 1994.)

an aversive emotional response to the poor returns of decks A and B. Unlike healthy participants, who show apprehension by sweating when they prepare to take a card from a bad deck, EVR showed no skin conductance response before selecting a card.

Single-neuron recordings in monkeys have shown that orbitofrontal cortex activity reflects the value of anticipated rewards. In a typical testing situation the monkey is seated in front of a pair of levers. A cue presented above one lever tells the monkey what reward

he will receive if he presses the lever. During the delay before the animal is permitted to respond, single neurons in the orbitofrontal cortex fire at a rate that reflects the monkey's preferences: If the animal likes raisins, most of the neurons will fire strongly when the monkey anticipates receiving a raisin (Figure 18–14).

When contextual factors alter the value the monkey attaches to a given food, the rate of neuronal firing in the orbitofrontal cortex shifts to reflect this fact. For example, neuronal responses decline as the monkey

Raisin (preferred)

Possible rewards: raisin and apple

Figure 18-14 Neurons in the orbitofrontal cortex of a monkey signal the subjective value of an expected reward. In the experiment illustrated here the monkey sat facing a display screen with two buttons. He initiated a trial by depressing a key with his hand. A symbol then appeared above one of the two buttons indicating a particular food would be available by pressing that button (instruction). After a delay a pair of squares appeared (trigger), a cue to the monkey to push one button. After a further delay the door of a food box opened, giving him access to the predicted reward. The histograms are from an orbitofrontal neuron that fired as the time for reward approached but only if the expected reward was the preferred food of a pair of alternatives. The monkey preferred raisins over apples and apples over cabbage (determined by his choices on trials, not shown, when he was allowed to choose between alternatives). Each histogram indicates the average firing rate across many trials. The rows of dots underneath each histogram represent action potentials fired on individual trials. (Reproduced, with permission, from Tremblay and Schultz 1999.)

becomes satiated. They can also increase or decrease when the subjective value of a given food is increased or decreased by pairing it with alternatives that the monkey likes less or more. A typical neuron fires strongly or weakly when the monkey anticipates a piece of apple, depending on whether the alternative is a less preferred food (a piece of cabbage) or a more preferred food (a raisin). The relation between single-neuron studies in the monkey and clinical observations of patients with orbital-ventromedial prefrontal damage is clear. The loss of neurons that signal the appetitive value of anticipated rewards might well give rise to decision-making problems such as difficulty in selecting a restaurant.

Limbic Association Cortex Is a Gateway to the Hippocampal Memory System

The cortex at the edge of the cortical surface forms a ring that is visible in a medial view of the hemisphere. Because it coincides with the edge (or limbus) of the cortical surface this ring is termed the *limbic lobe* or *limbic association cortex* (Figure 18–15).

Several decades ago it was thought that the limbic lobe association cortex, together with a collection of subcortical structures including the amygdala and hypothalamus, formed a unitary system, the "limbic system," that served homeostatic and instinctual drives (see Chapters 47 and 48). This classic description certainly applies to the orbital and ventromedial prefrontal areas described in the preceding section. These two areas belong to the limbic lobe, are strongly connected to the amygdala and hypothalamus, and contribute to

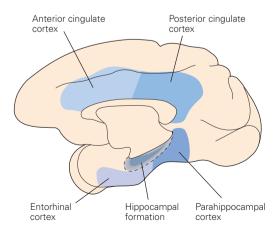

Figure 18–15 The limbic lobe includes the hippocampal formation. The hippocampal formation, including the hippocampus and subicular complex, plays a decisive role in forming long-term episodic memory. The functions of the other limbic areas on the medial surface are not well understood.

emotional processes. Other limbic lobe regions, however, are not primarily concerned with emotions. For example, the hippocampal formation which is part of the limbic lobe plays a critical role in episodic memory, the ability to remember past events including those with little or no emotional content.

The hippocampal formation consists of the hippocampus and the subiculum to which it is linked. The hippocampal formation mediates the formation of long-term memories and is critical for memory consolidation. Injury to it results in anterograde amnesia; patients are unable to form new memories but retain old memories. As we shall learn in Chapters 65 and 66, the hippocampus is thought to store memories temporarily through long-term synaptic plasticity. The hippocampus then transfers these memories to neocortex by inducing a replay in parietal, temporal, and frontal association cortex of activity patterns elicited by recent events. As a result, these cortical areas ultimately form their own stored representations of the events. Memories stored in the cortex are not dependent on the hippocampus and survive its loss.

The other divisions of the limbic lobe (Figure 18–15) serve as intermediaries between the hippocampal formation and the frontal, parietal, and temporal association areas. Their individual functions are not yet well understood.

An Overall View

The unimodal sensory and motor areas of the cerebral hemisphere occupy only a small part of the cortical sheet. Adjoining and surrounding them are large regions of association cortex where cognitive processes occur. Basic principles governing the organization and operation of association cortex have emerged from comparing the results of human clinical studies and physiological and anatomical studies in monkeys.

The two main principles of cortical organization are serial and parallel processing. In posterior cortex sensory information is extracted in a series of unimodal areas with increasingly complex functions. Each sensory modality (visual, auditory, or somatosensory) is processed in a chain of cortical areas leading outward from the primary sensory area. Parallel dorsal and ventral subdivisions of each modality process aspects of sensory information important for spatial behavior and for stimulus identification. Within each sensory modality, areas that process spatial information form a dorsal stream leading to parietal association cortex whereas areas that process feature information form a ventral stream leading to temporal association cortex.

The parietal association cortex, in addition to receiving convergent input from multiple sensory systems, is also strongly linked to motor areas in the dorsal frontal lobe. In humans injury to the parietal cortex results in disorders of body awareness, motor control, visual guidance of behavior, spatial vision, and spatial cognition. In monkeys parietal neurons fire in response to sensory stimuli and during motor behavior; their firing is selective for the spatial attributes of both objects and actions.

The temporal association cortex, in addition to receiving input from multiple sensory systems, is strongly linked to areas in the ventral frontal lobe concerned with emotion and cognition. In humans injury to the temporal lobe creates the agnosias (disorders of recognition), Wernicke aphasia (a disorder of speech comprehension), and the degradation of semantic memory. Thus the functions of temporal cortex include recognizing things and storing knowledge about them. In monkeys temporal neurons fire in response to sensory stimuli, and their firing is selective for the features of objects that are important for recognition.

The frontal association cortex consists of the dorsolateral and ventromedial prefrontal areas. These areas play a critical role in the executive control of behavior. The dorsolateral prefrontal cortex is important for maintaining intention. In humans injury to this region results in disorganized behavior and distractibility. In monkeys neuronal activity in this region represents working memory or plans of action.

The orbital-ventromedial prefrontal cortex contributes to motivational states by representing the emotional value of objects that might become targets of action. Injury to this cortex in humans results in a failure to properly value the expected consequences of an action. In monkeys neuronal activity in this region encodes the value of expected rewards.

The limbic association cortex, through its connections with the hippocampus, plays an important role in long-term episodic memory formation.

Cognitive Functions of the Premotor Systems

Direct Connections Between the Cerebral Cortex and Spinal Cord Play a Fundamental Role in the Organization of Voluntary Movements

The Four Premotor Areas of the Primate Brain Also Have Direct Connections in the Spinal Cord

Motor Circuits Involved in Voluntary Actions Are Organized to Achieve Specific Goals

The Hand Has a Critical Role in Primate Behavior

The Joint Activity of Neurons in the Parietal and Premotor Cortex Encodes Potential Motor Acts

Some Neurons Encode the Possibilities for Interaction with an Object

Mirror Neurons Respond to the Motor Actions of Others

Potential Motor Acts Are Suppressed or Released by Motor Planning Centers

An Overall View

In this chapter we turn to the higher-order functioning of the motor systems, by examining how the brain represents behavioral goals and how voluntary actions are planned to achieve those goals. To illustrate how the motor systems generate goal-oriented behavior, we focus on reaching and grasping, actions that are possible because of the prehensile hand.

The evolution of the prehensile hand greatly enriched the development of cognitive capacities in primates. Indeed, the two are interdependent. As the German philosopher Friedrich Engels wrote: "Man alone has succeeded in impressing his stamp on nature.

He has accomplished this primarily and essentially by means of the hand. But step by step with the development of the hand went that of the brain."

The prehensile hand radically changed the way in which primates relate to the external world; but the change occurred slowly, and required the evolution of cortical circuits for a variety of new specialized movements adapted to different objects. In his book *The Sensory Hand*, Vernon Mountcastle, one of the pioneers in the study of the connection between sensation and action, quotes Herbert Spencer (*Principles of Psychology*, 1885) on why the hand is so critical to understanding action:

All that we need notice here is the extent to which in the human race a perfect tactual apparatus subserves the highest processes of the intellect. I do not mean merely that the tangible attributes of things rendered completely cognisable by the complex adjustments of the human hands, and the accompanying manipulative powers have made possible those populous societies in which alone a wide intelligence can be evolved. I mean the most far-reaching cognitions, and inferences (even those) most remote from perception, have their roots in the . . . impression which the human hands can receive.

The final neural pathway for all bodily actions, including movement of the hand, is through motor neurons in the ventral horn of the spinal cord. These motor neurons are not simply responding to independently generated sensory information, however. The sensory information needed for action is the product of interaction between the motor systems and sensory systems. Under many circumstances, therefore, action

and perception are inseparable. Indeed, many sensory functions serve only to allow for the planning of motor acts. As we focus on and reach for a cup of coffee, our arm is controlled in a manner that is independent of conscious experience—we do not think about which movements to perform and which muscles to contract.

Perception of space, and even more complex cognitive acts, were once thought to be represented only in higher-order sensory and association areas of cerebral cortex. In a radical departure from previous thinking, we now believe that the premotor areas in the cortex may also have cognitive functions.

At the highest levels of sensory-motor interaction, neurons do not simply encode the physical features of the sensory stimulus or the force or direction of movement. Rather, they encode something more abstract that includes features of both the object and the movement: They encode the relationship between the body and the object with respect to a particular goal. For example, in anticipation of drinking they may represent a configuration of the hand in relation to graspable features of a cup.

Direct Connections Between the Cerebral Cortex and Spinal Cord Play a Fundamental Role in the Organization of Voluntary Movements

Although picking up a cup appears to be a simple mechanical action, the neural machinery underlying it is surprisingly complex, requiring a number of preparatory steps in the parietal and frontal premotor and motor cortex.

As discussed in Chapter 1, the discovery that electrical stimulation of different parts of the frontal lobe produces movements of the opposite side of the body had a major effect on thinking about localization of function in the brain. Brodmann's area 4, the area in the frontal lobe in which the lowest-intensity stimulation elicited movement, was designated the primary motor cortex (Figure 19–1). By systematically stimulating the primary motor cortex and attributing the movement elicited with each stimulus to the activation of neurons near the electrodes, researchers identified

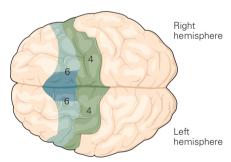

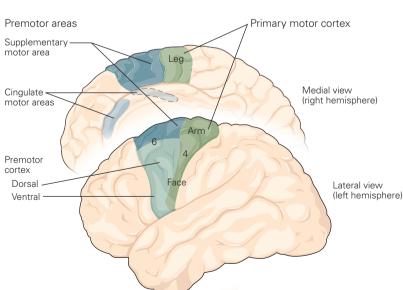

Figure 19–1 The cortical motor areas. The cortical motor areas lie largely in Brodmann's area 4 and area 6. Area 6 includes the supplementary motor area located largely on the medial brain surface, and the dorsal and ventral premotor areas located on the lateral surface. Area 4 includes the face, arm, and leg representations of the primary motor cortex. Additional motor areas are located in and around the banks of the cingulate sulcus.

groups of neurons that controlled movement of specific body parts and learned that these functional groups were distributed on the cortex in the form of a somatotopic map.

In recent years our understanding of the functional organization of the motor areas of the cerebral cortex has changed dramatically, and a new picture of the cortical control of movement is emerging. The functional organization of the primary motor cortex is not simply an isomorphic map of the body in which adjacent peripheral sites are represented in adjacent cortical sites. Instead, individual muscles and joints are represented in the cortex multiple times in a complex mosaic. This makes it possible for the cortex to organize combinations of elemental movements suitable to specific tasks.

Each muscle and joint is represented by a column of neurons whose axons branch and terminate in several functionally related spinal motor nuclei (this branching is minimal for cortical cells that control distal muscles because these muscles require more independent control). The cortical neurons also form synapses with interneurons in the spinal cord. These connections allow voluntary movements to switch on entire spinal circuits—the motor neurons, interneurons, and central pattern generators that execute reflex actions. These circuits are then able to integrate and convert local sensory input to motor output without further direction from cortical centers.

In the 1930s physiologists discovered that movement could also be elicited by stimulation of premotor areas. Brodmann's area 6 contains four main premotor areas that project directly to the spinal cord. Two areas lie on the lateral surface and two on the medial surface in Brodmann's area 6 (Figure 19–1.) Each of these four cortical areas may be viewed as a relay in a densely interconnected network that controls reaching and grasping by activating spinal motor circuits.

In contrast to neurons in the primary motor cortex, movement-related neurons in the premotor areas fire in connection with a variety of movements because these neurons encode a general goal-directed command such as "grasp the cup" or "pick up the raisin." Neurons called set-related neurons, common in premotor areas but relatively rare in the primary motor cortex, are more active in the absence of any overt behavior, such as during the delay between a behavioral cue and the behavior. Other neurons encode global sensorimotor transformations, such as "always move at 180 degrees from the visual stimulus." Thus, just as there is a hierarchy of spinal and supraspinal motor control, there is a hierarchy of representations of movement features within the different motor and premotor areas of the cortex.

To produce movement, signals from premotor and motor areas of the cortex must ultimately reach motor neurons in the spinal cord. The Dutch anatomist Hans Kuypers identified three motor pathways: a direct corticospinal pathway and two indirect pathways, the medial and lateral brain stem systems (Figure 19–2).

The historically well-known *corticospinal system* is involved in the control of all aspects of body and limb movement but has a special role in the fractionated movements necessary for skilled motor acts such as playing the piano or typing. Much of the control of fractionated movements is exercised by the primary motor cortex. Thus, a lesion of the primary motor cortex destroys the ability to oppose the thumb and first finger so as to pick up a raisin or grasp a cup. A patient with such damage is unable to move the fingers independently and can only grasp a cup clumsily.

In humans the corticospinal tract consists of approximately one million axons, of which 30% to 40% originate from neurons in the primary motor cortex. The rest of the axons have their origins mainly in the premotor and supplementary motor cortices, and in the parietal areas lying posterior to the precentral sulcus. Together, corticospinal axons from these various areas descend through the subcortical white matter, internal capsule, and cerebral peduncle. As the fibers of the corticospinal tract descend they form the medullary pyramids, prominent protuberances on the ventral surface of the medulla. Consequently the entire projection is sometimes called the pyramidal tract. Like the ascending somatosensory system, most fibers of the descending corticospinal tract cross the midline in the medulla, at the pyramidal decussation, to terminate in the spinal cord of the opposite side.

The motor information carried in the corticospinal tract is significantly modulated by a continuous stream of information from other motor regions as well as tactile, visual, and proprioceptive information needed to make voluntary movement both accurate and properly sequenced.

The *medial brain stem system* originates in portions of the reticular formation, vestibular nuclei, and superior colliculus. This system receives information from the cortex and other motor centers for the control of posture and locomotion. The *lateral brain stem system* originates from the red nucleus. It receives input from the cortex as well but is involved in the control of arm and hand movements.

Spinal motor circuits are not regulated solely by descending commands. Reflex circuits and pattern generators within the spinal cord can coordinate stereotyped movements such as stepping without

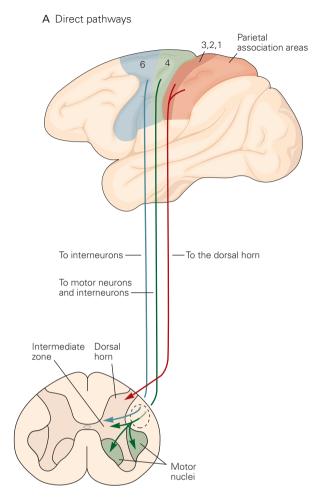

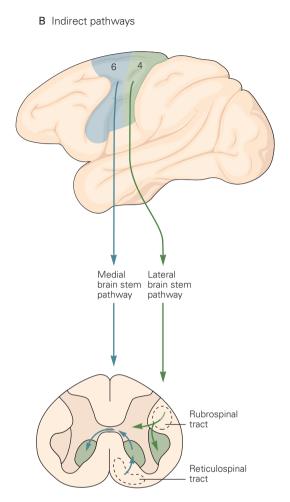

Figure 19–2 Direct and indirect motor pathways to the spinal cord. In the lateral view of the human brain; numbered areas are functional areas identified by Brodmann. The transverse section of the spinal cord shows three functional areas. The dorsal horn contains the sensory neurons of the spinal cord; the intermediate zone contains interneurons; and the motor nuclei zone contains the motor neurons that innervate the muscles.

A. The corticospinal tract, also called the pyramidal tract, originates in a vast region around the central sulcus that includes the parietal lobe and the posterior part of the frontal lobe (areas 4 and 6). Area 4, the primary motor cortex, is the only area of motor cortex that directly connects with spinal motor neurons.

descending signals (see Chapter 35). A newborn infant, whose descending pathways cannot yet control the spinal cord, is able to execute stepping movements when lifted into the air. Descending systems coordinate reflex and patterned movements generated by spinal motor circuits and can even create new patterns of muscle activation through direct action on motor neurons. This cortical control enables greater flexibility

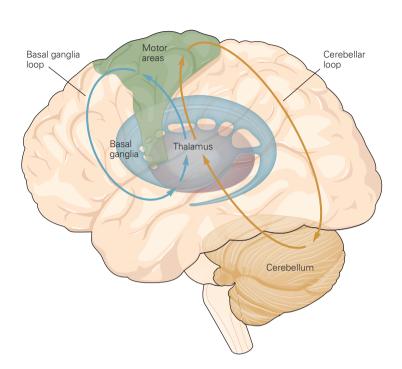

Area 6 comprises various subareas, most of which send fibers to interneurons in the intermediate zone of the spinal cord. The parietal lobe sends fibers to the dorsal horns.

B. Indirect pathways to spinal motor neurons originate in area 4 and area 6 and terminate in medial and lateral areas of the brain stem. The main components of the medial pathways are the reticulospinal, medial and lateral vestibulospinal, and tectospinal tracts; they descend in the ventral column and terminate in the ventromedial area of the spinal gray matter. The main lateral pathway is the rubrospinal tract, which originates in the magnocellular portion of the red nucleus, descends in the contralateral dorsolateral column, and terminates in the dorsolateral area of the spinal gray matter.

of movements than is possible through exclusively local coordination among the spinal motor circuits.

The cortical motor areas and brain stem in turn receive input from two major subcortical structures: the cerebellum and basal ganglia (Figure 19–3, and see Figure 16–9). These two structures provide feedback essential for the smooth execution of skilled movements and thus are important for motor learning,

Figure 19–3 The major subcortical brain systems that initiate and control motor actions. Both the basal ganglia and cerebellum influence cortical motor circuits through connections in the thalamus. The motor cortex determines which muscle groups are activated and the magnitude of force to exert. Based on inputs from the motor cortex, basal ganglia, cerebellum, and other brain stem nuclei, the spinal cord initiates appropriate muscle contractions to accomplish purposeful movement.

the improvement in motor skills through practice. The cerebellum and the basal ganglia store memory for unconscious motor skills through pathways that are separate from those used to store factual memories of events that can be recalled consciously (see Chapter 66).

The cerebellum receives somatosensory information directly from primary afferent fibers arising in the spinal cord as well as information about movement from corticospinal axons descending from the neocortex. The basal ganglia receive direct projections from much of the neocortex, which supply both sensory information and information about movement (see Figure 16–9).

The Four Premotor Areas of the Primate Brain Also Have Direct Connections in the Spinal Cord

In primates four functionally distinct premotor areas also send direct connections to the spinal cord (see Figure 19–1).

The two areas on the lateral surface are the *lateral ventral premotor area* and *lateral dorsal premotor area*. As we shall see later, the ventral premotor cortex mostly controls mouth and hand movements. Most of its neurons do not discharge in association with simple movements toward an object. They only become active during goal-directed actions such as grasping,

holding, or manipulating an object. The two areas on the medial surface are the *supplementary motor area*, which lies in the medial wall of Brodmann's area 6, and the *cingulate motor areas*, a group of motor areas buried in the cingulate sulcus. Similar premotor areas also exist in humans, but differences in size and sulcal patterns make it difficult to identify homologous areas with precision.

These four premotor areas are connected to the primary motor cortex. In addition, like the primary motor cortex, each premotor area has neurons that project to the brain stem as well as neurons that project directly to the spinal cord. Thus voluntary movements are controlled by descending signals from several cortical areas. For this reason, the task of generating limb movements is thought to be broken up into multiple subtasks, each managed in parallel by one of the several cortical motor areas.

These premotor areas also have dense reciprocal connections with the association areas in the posterior parietal cortex (Figure 19–4). These reciprocal connections constitute the visuomotor circuits that mediate different types of visually guided motor behavior such as mouth movements, arm reaching, and hand grasping.

Primates have remarkable visuomotor capacities. We can link the sight of an object with quite different actions. Seeing a cup of coffee, we can pick it up, drink from it, or throw it against the wall. As we shall

learn in greater detail in the chapters on vision, some visual pathways are concerned only with perception, whereas some are concerned with planning motor acts. In fact, these two kinds of visual information are processed in separate pathways originating in different areas of cortex: the ventral (what) and dorsal (where) visual streams (Figure 19–5).

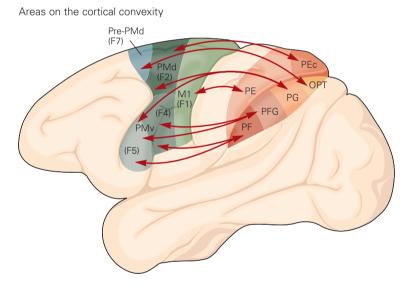

The *ventral stream* terminates ventrally in the inferotemporal lobe. It carries information that allows us to distinguish the visual properties of objects, an orange from a tennis ball, for example. Because the visual properties of the orange and the tennis ball are different, they are represented differently in the inferotemporal cortex, even though they may be the same size and occupy the same spatial location.

Charles Gross first demonstrated that the neurons in the inferotemporal cortex are highly selective for specific and complex visual stimuli. For example, some neurons are selective for individual faces, an extreme example of visual discrimination. Other neurons in the inferotemporal lobe near the superior temporal sulcus react selectively to the sight of movements of other individuals.

The *dorsal stream* terminates in the posterior parietal lobe and carries information that allows us to locate objects in space and to act on them. The dorsal stream has two branches: a dorsal (dorso-dorsal) branch and a ventral (ventro-dorsal) branch (Figure19–5B). The dorso-dorsal stream is involved in the control of movements. Damage of this pathway produces optic ataxia,

Figure 19-4 The premotor areas have rich connections with the association areas of the posterior parietal cortex. Functional areas in the posterior parietal lobe and motor areas of frontal cortex are shown in lateral views of the monkey brain. For illustration, the intraparietal sulcus is opened in the brain below. The new terms for frontal areas are indicated in parentheses. The new terminology, replacing that originally proposed by Brodmann, was advanced by Massimo Matelli and co-workers and derived from Constantino von Economo. It is based on gross anatomical location as well as cytoarchitectonic properties. The parietal areas are designated in von Economo's terminology by the letter P (parietal), followed by letters instead of numbers to indicate the cytoarchitectonically different areas. Areas PF and PFG roughly correspond to Brodmann's area 7b, areas PG and OPT to Brodmann's area 7a. Areas inside the intraparietal sulcus include the anterior, lateral, medial, and ventral intraparietal areas (AIP, LIP, MIP, VIP), as well as the PE intraparietal area (PEip) and visual area 6A (V6A).

F, frontal; M1, primary motor cortex; OPT, occipitoparieto-temporal; P, parietal; PMd, dorsal premotor cortex; PMv, ventral premotor cortex; Pre-PMd, predorsal premotor cortex.

Areas inside the parietal sulcus

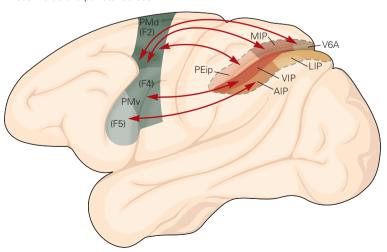

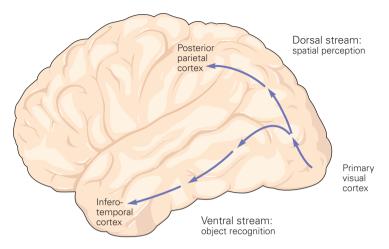

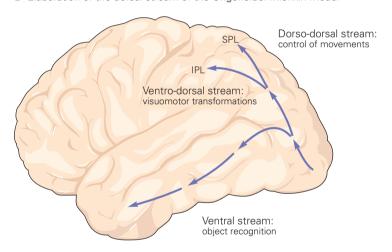

Figure 19-5 The ventral and dorsal streams of visual processing. The streams shown on a human brain are bidirectional but are shown as unidirectional for the sake of clarity. The original model of Leslie Ungerleider and Mortimer Mishkin (A) has been elaborated in a more recent model by Giacomo Rizzolatti and Massimo Matelli, which takes into account the subdivision of the dorsal stream into two branches (B). Of these two branches, the dorsal branch is involved in control of specific movements, as originally proposed by David Milner and Melvin Goodale, whereas the ventral one mediates the visuomotor transformations necessary for the organization of purposeful action, such as reaching and grasping, and perception of space and actions. The ventral branch also plays a role in interpreting the purpose of movements observed in others. (SPL, superior

parietal lobe; IPL, inferior parietal lobe.)

A Original Ungerleider-Mishkin model

B Elaboration of the dorsal stream of the Ungerleider-Mishkin model

a clinical syndrome in which the patient knows the location of objects but is unable to reach them properly. The ventro-dorsal stream is involved in visuomotor transformations necessary for interacting with objects, as well as space perception. The most common deficit following damage of this pathway is spatial neglect (see Chapter 17).

The idea that the dorsal stream is crucial not only for space perception, as traditionally thought, but also for the organization of action, derives from experiments by David Milner and Melvin Goodale on a patient with large lesions of the ventral visual stream. This patient had a dramatic dissociation between the capacity to distinguish geometric shapes conceptually and the capacity to act on objects. When asked to describe the orientation of a slot, the patient would

respond virtually at chance. However, when asked to insert a card inside the slot, the patient performed the action well, moving the card toward the slot in the correct orientation and inserting it accurately (Figure 19–6). Thus the visuomotor circuits of the dorsal stream alone are capable of guiding behavior.

Motor Circuits Involved in Voluntary Actions Are Organized to Achieve Specific Goals

Voluntary initiation of movement is one of the defining characteristics of animal behavior. Reflex actions are more or less stereotypic responses to external or internal stimuli. Voluntary actions are manifestations of centrally generated intentions to move; the goal—reaching

for a cup of hot coffee—determines a series of actions that will lead to its achievement.

Voluntary movements allow an animal to explore the world around it to satisfy not only immediate but also future needs. Unlike reflex behavior, the stimuli for voluntary behavior do not determine the response; they only set the occasion for it. Therefore, an animal may or may not respond to a stimulus, or it may respond to the same stimulus in different ways depending upon its needs. Under different conditions an animal may approach, avoid, or ignore the same stimulus.

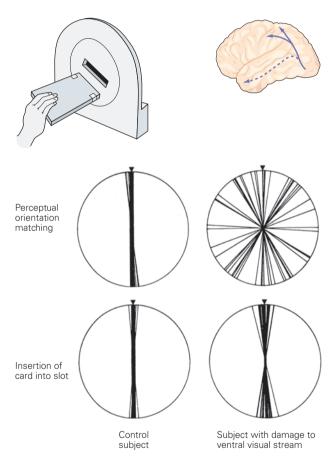

Figure 19–6 Damage to the ventral visual stream impairs conscious recognition of shape. A patient with visual agnosia caused by damage of the ventral visual stream (see Figure 19–5) and an age-matched control were tested on two tasks. Subjects were first asked to match the orientation of a handheld card with that of a slot placed in front of them. Polar plots illustrate the variability in orientation of the card. They then were asked to insert the card into the slot. Polar plots illustrate the orientation of the card as it was brought to the slot; the correct orientation has been normalized to the vertical orientation. (Reproduced, with permission, from Milner and Goodale 2002.)

The primate brain, particularly the human brain, is characterized by an enormous expansion of the cerebral cortex. This expansion correlates with an extraordinary increase of sensory, motor, and cognitive capacities. A large part of the expansion has occurred in three regions: the rostral part of the frontal lobe (the prefrontal cortex) and two posterior regions of cortex, the posterior part of the parietal lobe and the inferotemporal cortex.

As discussed in the preceding chapters, the posterior part of the parietal lobe and the inferotemporal cortex are association areas that integrate information from different sensory modalities. This association is essential for the formation of percepts, like space and objects. Indeed, patients with lesions in the parietal cortex typically have deficits in spatial perception, whereas patients with damage in the inferotemporal cortex have problems recognizing objects and faces.

Prior to 1970 deficits in spatial perception following parietal damage were attributed to the destruction of an area that was thought to encode a single internal representation of the external world. However, a series of anatomical and functional studies have revealed that the parietal lobe contains more than one representation of space and each of these representations is strikingly dependent on motor activity.

Jaana Hyvärinen assessed the responses of individual neurons in the inferior parietal cortex to sensory stimuli and during motor behaviors. He found that most neurons respond to sensory stimuli that occur in specific locations and often to stimuli of different modalities, both visual and somatic stimuli for example. Other neurons discharge in association with motor acts. Actions carried out with different parts of the body are represented in different but overlapping zones.

This orderly representation of movements is similar to the somatotopic arrangement of somatosensory inputs in the postcentral gyrus (see Chapter 17). Neurons in the rostral part of the inferior parietal lobe discharge in relation to movements of the mouth; neurons in the central part of this lobe fire in association with hand and arm movements; those located more caudally fire in relation to eye movements. Some neurons in this region respond to objects that lie close to the subject, in the space within arm's reach (peripersonal space), without necessarily requiring that the movement actually occur. Other neurons prefer stimuli located far from an individual's body. Neurons that respond to objects in peripersonal space are located mostly in the part of the inferior parietal lobe where mouth and hand movements are represented, whereas neurons that respond preferentially to objects further away from the body are found mostly in the part of the parietal lobe where eye movements are represented.

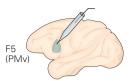

The Hand Has a Critical Role in Primate Behavior

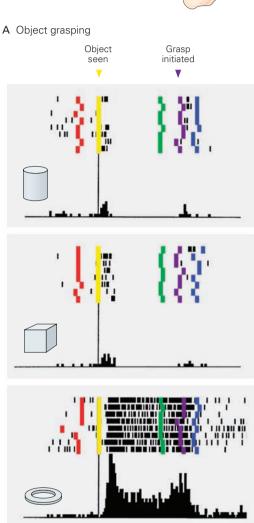

What are the critical steps involved in grasping? The neural control of grasping has been studied by Hideo Sakata and Giacomo Rizzolatti. Sakata investigated the anterior intraparietal area (AIP) (see Figure 19–4), the region where previous studies had identified neurons that discharge in association with grasping movements. Sakata and his colleagues recorded the activity of individual neurons in alert monkeys trained to grasp different types of objects, each requiring a specific type of grip. The monkeys carried out these tasks under normal light, using visual guidance, but also in the dark, using memory. In this way Sakata and his colleagues discovered that the neurons in this area fall into three main classes: motor-dominant, visual-dominant, and visual-and-motor neurons.

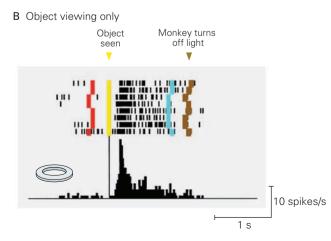

Motor-dominant neurons discharge equally well during movements performed in light and in the dark. Visual-dominant neurons discharge only during movement performed in light. Visual-and-motor neurons fire during movements performed in both light and dark but their discharge is stronger in the light. Most visual-dominant and visual-and-motor neurons also respond when the monkey looks at an object but does not reach for it. Neurons that discharge selectively during manipulation of an object also discharge selectively during visual fixation of that object without movement. Based on this finding Sakata proposed that neurons in the anterior intraparietal area are involved in transforming sensory representations of objects into motor representations of how to grasp them.

Rizzolatti and co-workers next recorded the activity of neurons in a sector of the ventral premotor cortex of monkeys—area F5 within Brodmann's area 6 (see Figure 19–4)—while the animals performed a variety of actions. They found sets of neurons that discharged in association with different types of hand actions: grasping, holding, and manipulating. Some were active regardless of how the object was grasped. Most, however, discharged only when the monkey used a specific type of grip. The most commonly represented grip types were the precision grip (grasping with the index finger and thumb, typically used for small objects), whole-hand grasp (clutching, used for large objects), and finger grasp.

Surprisingly, a considerable fraction of neurons in area F5, called *canonical neurons*, also discharged when the monkey simply observed an object, whether or not the object was subsequently grasped (Figure 19–7). Thus these neurons discharged in response to presentation of an object even though the neuron did not have anything to do with preparation to grasp the object.

Most canonical neurons were selectively activated by the presentation of objects of a certain size, shape, and orientation. Neurons that discharged during a precision grip (performed with the index finger and thumb) also fired in response to the presentation of small objects, whereas neurons that discharged during whole-hand grasping also fired in response to the presentation of large objects.

What explains the behavior of canonical neurons? The fact that their activity is not related to motor planning and their responses are selective for certain objects and not others rules out nonspecific factors such as attention or intention, because nonspecific factors would have the same effect for all presented objects. Rather the presentation of an object seems to trigger the translation of the object's physical properties into a *potential motor act*.

The Joint Activity of Neurons in the Parietal and Premotor Cortex Encodes Potential Motor Acts

Some Neurons Encode the Possibilities for Interaction with an Object

The studies of the parietal and premotor canonical neurons led Michael Arbib, and subsequently Rizzolatti and Giuseppe Luppino, to formulate a new model of how sensory representations of objects are transformed into hand movements.

Figure 19–7 (Opposite) Canonical neurons respond both when the animal is grasping and when it is simply viewing an object of a particular shape. Recordings were made from a neuron in the F5 portion of the ventral premotor area while a monkey was presented with objects of different shapes. In the raster plots each row represents a separate trial and each tick in the row indicates the discharge of the neuron. Below each plot the neuronal activity is summarized in a histogram. The experimental protocol is as follows. A red light-emitting diode (LED) is turned on and the monkey fixates it (red ticks). The monkey then presses the key that turns on a light inside the training box (yellow), illuminating an object. The red LED turns green, cueing the monkey to grasp the object (green). The monkey releases the key and starts reaching (violet), and then finally grasps the object (blue). (Reproduced, with permission, from Murata et al. 1997.)

A. The response of the neuron to an image of a ring is more vigorous than its responses to a cube or a cylinder. Peaks in neuronal activity occur both when the monkey sees the object and when the monkey grasps it. After the object is grasped, the neuron's activity virtually ceases.

B. The neuron is also activated when the monkey views the object with no intention to act on it. In this part of the experiment the monkey again fixates the LED and turns on a light to make the object visible but then follows a cue (light blue) to simply turn off the light (brown).

Their model is based on the functional significance of the responses of visual-dominant and visual-and-motor neurons in the anterior intraparietal area to the presentation of three-dimensional objects. Their thinking about these responses was influenced by the notion of *affordance* introduced several years ago by the psychologist James J. Gibson. According to Gibson the sight of an object triggers an immediate and automatic selection of those properties of the object that allow one to interact with it. These properties, or affordances, are not the visual aspects of the object (shape, mass, color, etc.) but the *pragmatic opportunities* that the object affords the observer.

As we have seen, aspects of visual stimuli that are useful for action are analyzed in the dorsal stream of the visual system. Based on the extensive elaboration of an object's properties in the extrastriate visual areas of the dorsal stream beginning in V₂, the visual-dominant and visual-and-motor neurons in the anterior intraparietal cortex are able to encode the object's affordances. This information is then sent to F5 neurons that encode potential motor acts. An F5 neuron can transform a given affordance into an appropriate potential motor act because of the congruence of its response to the affordance and the motor act it controls. Object becomes action.

In real life objects usually have more than one affordance and may be grasped in several ways. How does the brain determine which is optimal? Behavioral analysis of grasping reveals that nonvisual factors determine the choice of affordance and thus how an object will actually be grasped. These factors relate both to what the object is for and the individual's intent at that moment. A cup is a simple example. The cup has three major affordances: the handle, the top, and the body. If the cup is recognized as a cup and the person wants to use it in the way a cup is commonly used, the person will grasp it by the handle. However, if the person wants to move the cup or give it to someone, the cup may be taken not by the handle but by its body or its rim (Figure 19–8).

Thus a more complete (and realistic) model of the grasping circuit involving the anterior intraparietal area and the premotor area F5 must assume that the circuit extracts automatically not one but all the affordances of an object. A specific affordance will be selected according to the information the circuit receives about the meaning of the object and the individual's intention.

As far as the *meaning* of the object is concerned, the ventral visual stream (Figure 19–8) is specifically dedicated to description of objects. This stream ends in the inferotemporal lobe, which is richly connected

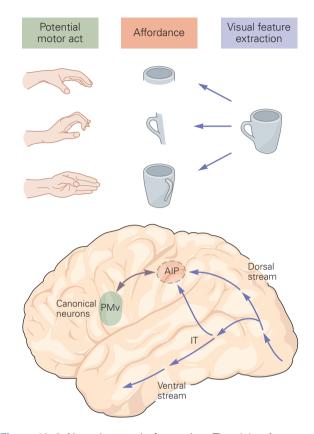

Figure 19–8 Neural control of grasping. The sight of a cup automatically triggers the motor act appropriate for grasping it. The brain centers involved in grasping are indicated below, and the operations carried out by them are summarized in the upper part of the figure. Affordances are not the visual aspects of the object (shape, size, color, etc.) but the *pragmatic opportunities* that the object affords the observer. (AIP, anterior intraparietal area; PMv, ventral premotor cortex; IT, inferotemporal cortex.)

reciprocally with the inferior parietal lobe, including the anterior intraparietal area. It is likely that these connections convey to the parietal lobe the semantic properties of an object; this information, as well as the motor use of the object specified in the premotor circuits, is the basis for the selection of an appropriate affordance consistent with the standard uses of the object.

The anatomical substrate for selecting affordances on the basis of the individual's current goal could be the input to the inferior parietal lobe from the prefrontal lobe, where long-term motor planning occurs. Thus when an unconventional use of an object is intended, the prefrontal input could override the selection of *standard* affordances and select those affordances that are congruent with the individual's intention. For example, if an individual wants to throw a cup instead

of drinking from it, the affordances presented by the body of the cup or its top will be selected rather than the affordance presented by the handle.

Mirror Neurons Respond to the Motor Actions of Others

Canonical neurons discharge both when the monkey acts on an object and when it simply looks at the object without acting. In both cases these neurons fire in much the same manner and send the same signal to other neural centers. The firing of the neuron in the absence of an overt movement represents therefore a potential motor act: This activity occurs in a circuit that plans a movement but does not trigger a motor command. Potential motor acts afford an individual the freedom to choose whether or not to respond to a stimulus or simply hold it in memory.

Potential motor acts have an entirely different significance in a set of extremely interesting visuomotor neurons, the *mirror neurons*, in area F5. These neurons, like all neurons in F5, discharge during specific motor acts such as grasping, tearing, or holding. In addition, they also fire when the monkey observes another individual (human or monkey) performing the same motor act. They do not discharge in response to mere object presentation. In other words, these neurons represent the action done by another individual as a potential motor act.

What may be the function of these neurons? One attractive idea is that individuals know the outcome of the motor acts they plan. Thus, when the mirror neurons discharge in response to a motor act done by another individual, the observer understands what the other individual is doing because the observed action elicits in his premotor cortex a motor plan whose outcome is known to him.

At first glance it may seem strange that our motor faculties might be involved in understanding what others are doing, what their intentions are. But how else could we obtain this information? Although our visual system provides us with a description of the overt aspects of an action, it does not tell us what the action means, what its purpose is. Mirror neurons could in principle provide us with an experience-based understanding of observed actions, a basis for understanding the *intention* of others (see Chapter 38).

An essential step in the biological evolution of social cognition is our ability to interact with each other in a meaningful and constructive way. When you and I talk, you not only know the content of your own mind but also have a sense of what I am thinking and how I am reacting. A defect in social cognition

may contribute to autism, a serious developmental disorder in which a child's ability to communicate socially is impaired. Normal communication requires, in addition to familiarity with language and the ability to express oneself, certain sensitivity to the thoughts and feelings of the person with whom one is communicating. One of the central features of autism is difficulty in understanding the perspectives, thoughts, ideas, and intentions of another person.

The mirror neurons are probably the most basic system the brain has for understanding others' intentions. Other cortical regions, such as the region near the superior temporal sulcus and some rostral medial cortical areas, also play a role in understanding another's intentions, especially when complex reasoning is required.

Potential Motor Acts Are Suppressed or Released by Motor Planning Centers

The representation of potential motor acts by the nervous system raises a further question. What prevents a potential motor act from being executed? Are there control mechanisms inhibiting or facilitating implementation? Damage to certain premotor cortical areas, or the motor cortex, results in neurological syndromes that strongly suggest that there are such controls. Some of these behavioral disorders include difficulty in initiating movements or making movements that are not consciously intended.

A particularly telling example is the *utilization* behavior syndrome. Individuals with this syndrome pick up objects in an almost compulsive way. Once they observe an object, they immediately grasp it, even if it belongs to another person or to the doctor examining them. This syndrome may result from impaired restraint of the potential motor acts elicited by objects.

A key feature of voluntary motor behavior is that certain motor acts are executed while others are restrained. Voluntary action depends on sequencing elementary movements to form purposeful action. This ability is the prerequisite for many of our daily actions such as typing, using a computer, playing a musical instrument, and even speech. Karl Lashley called the task of sequencing motor actions the "serial order problem" of motor behavior. The sequence of motor actions is thought to involve parallel computations in multiple cortical areas and subcortical nuclei, including the basal ganglia and the supplementary motor area.

Neurons in the supplementary motor area are involved in the planning, generation, and control of sequential motor actions. Thus, when monkeys were trained to perform different sequences of three simple elemental arm movements—push, pull, and turn—some

neurons in the supplementary motor area were active before any movement occurred but only when a specific sequence was planned. For example, a neuron could be active prior to the performance of a pull-turn-push sequence but not before a pull-push-turn sequence. Other neurons were active while a particular movement was performed but only if the movement was preceded or followed by another specific movement.

An Overall View

The brain recognizes objects and carries out actions in ways no existing computer can even begin to approach. Recognizing a face and appreciating a land-scape are amazing computational achievements that require sophisticated processing of complex information. Indeed, all our perceptions are analytical triumphs. However, even more amazing is how all this perceptual analysis is integrated with motor circuits for even the simplest voluntary actions such as picking up a cup of coffee.

The final neural pathway for any action that determines the force exerted by individual muscles is through the motor neurons in the ventral horn of the spinal cord. Nevertheless, in sophisticated animals like monkeys or humans, actions are not produced by the spinal cord alone. Several sensory and motor regions in the brain are also involved.

The planning and execution of voluntary movement relies on sensorimotor transformations in which representations of the external environment are integrated with intentions and motor programs. This integration is the product of premotor and primary motor areas operating in conjunction with sensory and association areas of the cerebral cortex. An example of this is the communication between parietal and motor areas during visually guided reaching.

In our everyday experience it seems we perceive an object before interacting with it; and thus intuitively we might expect the brain to work in this sequential way. According to this model perceptual mechanisms first generate a unified representation of the external world, cognitive processes use this replica of the world to decide on a course of action, and finally an action plan is relayed to the motor systems for implementation.

As we have seen, this intuitive view does not capture the reality of how the brain decides and executes movement. In fact, a novel behavior requires simultaneous processing in multiple motor and sensory areas because the behavioral action is continuously monitored for errors and modified. As the behavior becomes more accurate, the need for sampling of the

sensory inflow and updating of the motor program decreases—the need for the computational power of large networks lessens. Thus, for example, the presupplementary motor area is active during the learning of a behavior but becomes less active as learning progresses. After long periods of practice, when the behavior becomes automatic, activity in the presupplementary motor area ceases.

Functional Imaging Has Limitations

An Overall View

THE ABILITY OF NEURO-IMAGING to observe areas of the human brain that are active during cognitive processes has helped to stimulate the current interest in the biological underpinnings of cognitive functioning. Because invasive experiments cannot be done ethically on humans, research on the biological basis of cognitive function was until quite recently confined to laboratory animals and clinical studies of patients with cognitive disorders.

The development of techniques such as functional magnetic resonance imaging (fMRI) has made it possible to study human subjects, affording unprecedented views of the complexities of the intact working brain. Imaging of the living brain allows us to explore the behavioral significance of local neural circuits, such as cortical columns, as well as observe large-scale systems of interconnected brain regions concerned with specific mental processes such as seeing, hearing, feeling, moving, talking, and thinking.

Functional Imaging Reflects the Metabolic Demand of Neural Activity

Functional Imaging Emerged from Studies of Blood Flow

Functional imaging evolved out of seminal studies in the late 1940s by Seymour Kety and Carl F. Schmidt, who succeeded in measuring blood flow in the living brain. Although Charles S. Roy and Charles S. Sherrington earlier had found a relationship between blood flow and brain metabolism, Kety and Schmidt were the first to quantify cerebral blood flow noninvasively.

To accomplish this task, Kety and Schmidt measured the rate of cerebral blood flow by having subjects inhale nitrous oxide, a metabolically inert gas, and measuring its outflow concentration from the jugular vein (Box 20–1). In a series of landmark studies they evaluated how blood flow from the intact brain varied in different metabolic states, such as sleep and wakefulness, and in so doing they laid the foundations for modern functional imaging.

These early experiments measured only the total level of activity of the entire brain, however. They could not provide information about which parts of the brain were active, nor could they tell us whether some brain areas became more active while others became less active under set conditions.

A significant advance came in the 1970s with the introduction of positron emission tomography (PET) by Michel Ter-Pogossian, Michael Phelps, and Louis Sokoloff (Box 20–2). In the 1980s Marcus Raichle collaborated with Michael Posner to visualize the brain

Box 20–1 Application of the Fick Principle to Brain Metabolism

Devised as a technique for measuring cardiac output by Adolf Eugen Fick, the Fick principle states that an organ must receive blood at a rate that is equal to the rate at which the organ metabolizes a constituent of blood, divided by the concentration of that constituent.

The essence of the Fick principle is that blood flow to an organ can be calculated using a marker substance. The principle may be applied in many ways. For example, if blood flow to an organ is known, together with the arterial and venous concentrations of the marker substance, then the uptake or metabolism by the organ may be calculated. Seymour Kety and Carl F. Schmidt adapted the Fick principle so that it could be applied to the brain and showed that it can be used to measure cerebral blood flow. The Fick Principle has also been used to explain BOLD (Blood Oxygen Level Dependent) fMRI. BOLD fMRI detects changes in deoxyhemoglobin content within a unit volume of brain. As can be derived from the Fick principle, deoxyhemoglobin concentration is proportional to the cerebral metabolic rate of oxygen (CMRO₂) divided by cerebral blood flow (CBF).

activity of subjects engaged in complex tasks of thought and language, thereby demonstrating that PET can be used to explore cognitive functioning.

A further advance in functional imaging occurred in 1990 when Seiji Ogawa and David Tank discovered that magnetic resonance imaging (MRI) can be made sensitive to changes in deoxyhemoglobin that are caused when neurons change their metabolic rates. They exploited the fact, first discovered in 1936 by Linus Pauling, that when oxyhemoglobin is converted to deoxyhemoglobin (by stripping hemoglobin of its four oxygen molecules), it becomes paramagnetic.

In particular, they showed that in MRI images of the hippocampal formation of anesthetized rodents areas of increased vascularity appeared darker than areas with less vascularity. When rodents breathed 100% oxygen, the image intensities in the hippocampus were brighter, thereby suggesting that these differences in intensity were caused by changes in blood oxygenation. Finally, Ogawa went on to link these differences in image intensity with metabolism. He found that systematic pharmacological alteration of basal brain metabolism in anesthetized animals induced a corresponding increase in the image intensity (Box 20–3).

In brain regions with increased metabolism the flow of oxygenated blood is greater than the consumption of oxygen, and thus leads to a relative decrease in deoxyhemoglobin. MRI areas with increased metabolism and flow of oxygenated blood appear brighter than regions that are not experiencing increased metabolism (Box 20–3). This form of functional MRI has been termed BOLD (blood oxygen level dependent) imaging.

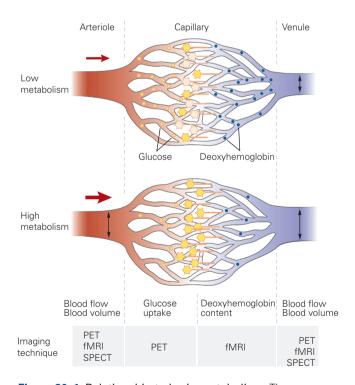

Figure 20–1 Relationship to brain metabolism. The energy metabolism of neurons is influenced by changes in synaptic activity or synaptic strength. Shifts in metabolism are associated with local increases in cerebral blood flow, glucose uptake, and cerebral blood volume, and a decrease in deoxyhemoglobin content. These different changes are detected with different techniques. Imaging techniques: fMRI, functional magnetic resonance imaging; PET, positron emission tomography; SPECT, single-photon emission computed tomography.

Box 20–2 Positron Emission Tomography

Positron emission tomography (PET) imaging requires the introduction into the brain of substances tagged with radionuclides that emit positrons (positively charged electrons). Commonly used substances are $^{11}\mathrm{C}$, $^{18}\mathrm{F}$, $^{15}\mathrm{O}$, and $^{13}\mathrm{N}$. The synthesis of compounds with these radionuclides does not result in the loss of biological activity; thus $\mathrm{H_2^{15}O}$ behaves like $\mathrm{H_2^{16}O}$ and $^{18}\mathrm{F}$ -deoxyglucose like deoxyglucose.

The radionuclides are produced in a cyclotron, which adds protons into the nuclei of atoms. For example, bombarding oxygen with hydrogen ions makes ¹⁸F. Incorporation of an extra proton into the nucleus produces an unstable nucleus.

These unstable radionuclides can be detected when the extra proton spontaneously breaks down into

two particles: (1) a neutron, which remains within the nucleus because a stable nucleus can contain extra neutrons, and (2) a positron, a particle that travels away from the nucleus at the speed of light, dissipating energy as it goes. The positron eventually collides with an electron, and the collision leads to their mutual annihilation and the emission of two gamma rays (high-energy photons) in opposite directions (Figure 20–2A).

PET scanners contain arrays of gamma ray detectors (scintillation crystals coupled to photomultiplier tubes) encircling the subject's head (Figure 20–2B). The two gamma rays emitted by the annihilation of a positron and electron ultimately reach pairs of coincidence detectors that record an event when, and only when, two gamma rays are detected simultaneously.

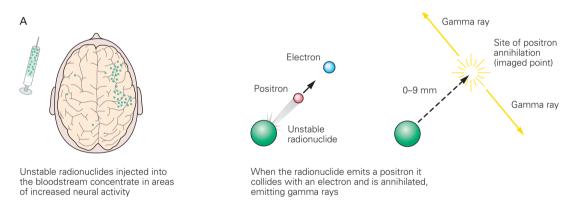

Figure 20–2A Emission of gamma rays. The nucleus of an unstable radionuclide emits a positron. The positron travels a certain distance before it collides with an electron and is annihilated, emitting two gamma rays that travel in precisely opposite directions. The site of positron annihilation that is imaged may be a few millimeters from the site

of origin. For example, the average distance between the site of origin and annihilation is 2 mm for ¹⁸F and 3 mm for ¹⁵O. The distance between the emitting nucleus and the site where the positron is annihilated is an absolute limit on the spatial resolution of PET scan images. (Adapted, with permission, from Oldendorf 1980.)

Functional Imaging Reflects Energy Metabolism

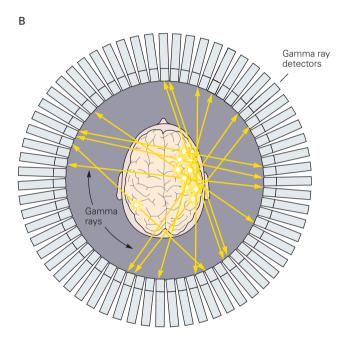

As these discussions make clear, functional imaging does not measure neural activity but rather reflects energy metabolism, best defined as the rate at which mitochondria produce adenosine triphosphate (ATP). Because direct imaging of ATP production is difficult, functional imaging assesses correlates of energy

metabolism that can be visualized with clinical imaging devices (Figure 20–1).

A surprisingly large amount of a neuron's total energy metabolism, approximately one-half, is devoted simply to maintaining the resting membrane potential—the electric potential across the cell membrane. Therefore any shift in the membrane potential will affect the rate of energy metabolism and influence functional imaging

A coincident pair of gamma ray emissions is detected along a line in one plane or slice. The site where the positron is annihilated is the site detected by the scanner. Multiple positron-electron annihilations are pinpointed by monitoring coincident gamma rays in multiple slices. Clusters of annihilations indicate increased neural activity, which is mapped onto the brain in the final PET image (Figure 20–2C).

The distance between the site of annihilation and the emitting nucleus, which can be several millimeters, limits the spatial resolution of the method, which is typically 6 to 8 mm. The temporal resolution of PET imaging is limited by the rate at which positrons are emitted, which ranges from minutes to hours depending on the radionuclide used and the compound in which it is incorporated.

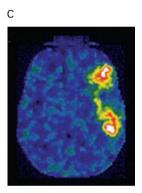

Figure 20–2B PET scanners contain an array of gamma ray detectors encircling the subject's head. Only gamma rays that are detected simultaneously by diagonally placed detectors are recorded. (Adapted, with permission, from Oldendorf 1980.)

Figure 20–2C PET image. PET produces an image showing the areas of heightened neural activity as revealed by the radionuclides.

measures. The membrane potential changes when a cell fires an action potential and also in response to subthreshold excitatory or inhibitory synaptic potentials.

The remaining half of a neuron's energy metabolism is devoted to other biochemical processes, and alterations in these pathways also affect functional imaging measures, although typically on a slower time scale. These biochemical processes include all of

the molecular reactions required for normal synaptic function: vesicle recycling, recruitment of second-messenger cascades, local protein synthesis, axonal transport, and transmitter release. Thus functional imaging in principle can measure the transient effect an external stimulus has on the electrical activity of neurons, as well as the more permanent effect of a disease process on neuronal biochemistry.

Box 20-3 Functional Magnetic Resonance Imaging

The development of functional magnetic resonance imaging (fMRI) emerged from a chain of discoveries that began in 1937 with the description of molecular beam magnetic resonance by Isidor Rabi and the discovery in 1945 of nuclear magnetic resonance (NMR), made independently by Edward Purcell and Felix Bloch. In 1949 Erwin Hahn observed that NMR decays differentially depending on the chemical makeup of an object, the key phenomenon that has made fMRI possible.

MRI scanners consist of several components. The first component is a superconducting magnet that provides a powerful and very uniform magnetic field (1.5 tesla for a standard clinical MRI scanner). Each water proton in the body rotates around its axis and acts like a small bar magnet. Water protons normally have random directions so the tissue essentially has no net magnetization. However, when placed in a magnetic field the protons become aligned (Figure 20–3A).

The second component is a *radio frequency coil* (or RF coil), a specially designed coil of wire placed near the subject. A brief, rapidly alternating electrical current in the RF coil generates a rapidly varying magnetic field because of Ampere's law. This second magnetic field is superimposed with the scanner's main magnetic field. The alternating electrical current in the RF coil is called a radio frequency pulse (or RF pulse) because it alternates at a frequency comparable to FM radio frequencies.

The magnetic field induced by the RF pulse causes the protons to start wobbling around their axes (Figure 20–3A), much as a spinning top wobbles around its axis when the force of gravity competes with its spin. This wobbling is called precession. The protons continue to precess after the RF pulse has been turned off.

Summed across all of the individual water protons, the precession creates a rotating magnetic field that changes in time (Figure 20–3A) and, according to Faraday's law, generates an alternating electric current

back in the RF coil. It is this electric current that is measured in MRI (Figure 20–3B).

The amplitude of the measured electric current decays over time at a rate that is dependent upon a number of factors, including the type of tissue in which the protons are embedded. Thus, differences in tissue type appear as different intensities in the resulting images.

The third component of an MRI scanner is the *magnetic gradient coils*. One of the most important developments in MRI is the ability to make three-dimensional images of the body. This is accomplished by using magnetic gradients, magnetic fields in which the strength of the field changes gradually along an axis.

It is beyond the scope of this chapter to explain in detail how two-dimensional images (or three-dimensional volumes) are acquired with MRI, but the basic idea is that controlling the magnetic gradients allows one to measure the MRI signal (the electric current in the RF coil) at a large number of adjacent locations, each corresponding to a small volume (or voxel) of tissue.

Functional MRI primarily measures changes in the relative amount of deoxyhemoglobin within each voxel (Figure 20–4). When neurons are active, the supply of oxygenated blood to the active region increases. For reasons that are still unclear, the delivery of oxygenated hemoglobin is greater than local oxygen consumption, resulting in a greater proportion of oxygenated to deoxygenated hemoglobin.

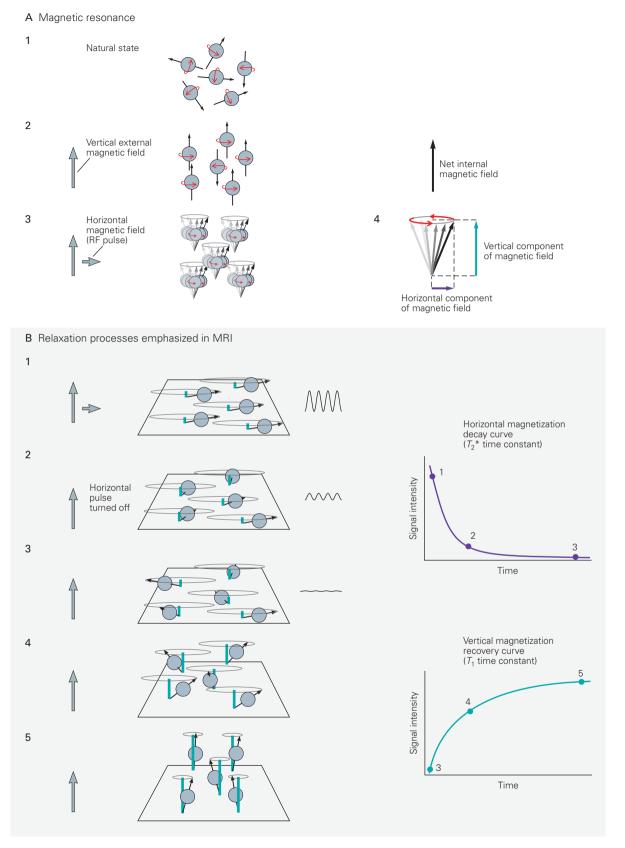

Oxygenated and deoxygenated hemoglobin have different magnetic properties. Hemoglobin contains iron, which is exposed when oxygen is stripped from the hemoglobin molecule. The presence of deoxyhemoglobin introduces an inhomogeneity in the nearby magnetic field. Some water protons (those that are near a deoxyhemoglobin molecule) now experience a magnetic field strength that is slightly different from the other water protons.

Figure 20–3 (Opposite) Magnetic resonance imaging.

A. Water protons spin around their axes, creating individual magnetic fields with random directions (1). When a vertical magnetic field is applied to the tissue, the protons align with it to create a net magnetic field that is also vertical but very small and difficult to detect (2). A radio frequency pulse applied in a second (horizontal) direction makes the protons wobble, or precess, around their vertical axes (3). Summed across all of the individual water protons, this creates a net magnetic field that changes in time and gives rise to an electric current that is ultimately measured in MRI (4).

B. An MRI measurement begins by placing the subject in a vertical magnetic field. With the protons aligned vertically, a horizontal radio frequency pulse is applied to

tip the protons so that they rotate in the horizontal plane synchronously, or "in phase" with one another (1). The horizontal pulse is then turned off (2), and the rotating protons begin to move out of phase with one another—they "dephase." Dephasing occurs relatively quickly and leads to a decrease or decay in the measured current. The time constant of this decay is called T_2 * (approximately 30 ms). After withdrawal of the horizontal pulse the protons realign with the vertical magnetic field (3–5). This "righting" or recovery of the vertical magnetization occurs more slowly than the dephasing. The time constant of the recovery is called T_1 (several seconds). The entire process can be repeated many times to yield a time series of measurements that reflect changes in the rates of decay and recovery.

Box 20–3 Functional Magnetic Resonance Imaging (continued)

Greater inhomogeneity causes the protons to desynchronize more rapidly resulting in a more rapid decay time (T_2*) . When there is an increase in oxygenated blood in areas with greater neuronal activity, and hence a more homogeneous magnetic field, the result is a longer T_2* decay time, and brighter image intensity.

Like PET scanning, fMRI is sensitive to the increased blood flow associated with neural activity. This technique has several advantages over PET scanning, however. It requires no injection of foreign substances into the bloodstream (fMRI uses endogenous hemoglobin as its marker). It also offers finer spatial and temporal resolution than PET.

For example, fMRI has been used to visualize the ocular dominance columns in human V1, which requires a spatial resolution of less than a millimeter, and it has been used to estimate differences in the timing of neural activity with a temporal resolution of approximately 100 ms. Sub-millimeter and sub-millisecond resolutions are not yet routine practice but have been demonstrated convincingly. The fMRI image in Figure 20–4 was acquired with a spatial resolution of 1 mm.

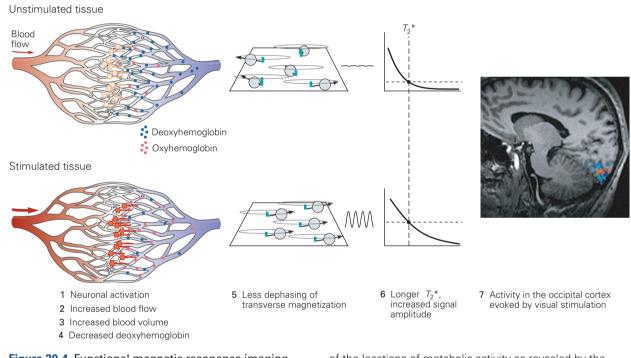

Figure 20-4 Functional magnetic resonance imaging. An increase in neuronal activity results in an increased supply of oxygenated blood. This decreases the deoxyhemoglobin concentration, causing dephasing to occur more slowly and hence slowing down the decay of the measured electric current. The result is an fMRI image

of the locations of metabolic activity as revealed by the changes in deoxyhemoglobin concentration. Colors in the image indicate regions of visual cortex that responded to visual stimuli placed at particular locations in the visual field. (fMRI image reproduced, with permission, from Souheil Inati and David Heeger.)

Functional Imaging Is Used to Probe Cognitive Processes

By visualizing the brain at work, functional imaging has transformed cognitive neuroscience. We will illustrate some insights derived from functional imaging by considering one of the field's ultimate questions—the nature of consciousness.

The idea is quite simple: By comparing brain activity between conscious and unconscious states we should be able to identify brain regions in which the activity is correlated with consciousness. Because

systematically manipulating consciousness is not trivial, translating this logic into a scientific experiment is difficult. To accomplish this task, scientists have relied on the fact that exposure to the identical external stimulus can alternately evoke a conscious or unconscious experience depending on other controllable factors. For example, as you read this chapter you have blinked numerous times; nevertheless, although your brain has recorded the flickered light caused by blinking, your consciousness has not. Now, once brought to your attention, you become aware of the perceptual effects of blinking (in fact, it is now difficult for you to suppress this awareness).

Just as sensory stimuli can be processed with and without conscious perception by the brain, the recall of objects from memory can also be conscious or unconscious. Consider running into someone you met once before. Viewing the person's face may activate conscious recall of the initial meeting—the place, the time, the person's name. Or, as is often the case, you might sense that the face is familiar, but you cannot quite connect it to a time or place—the face simply does not evoke conscious recall of the initial meeting. Even worse, you might not consciously recognize the face, even though (as can be demonstrated) some regions of your brain are responding unconsciously to the face (as if your brain remembers, but you do not).

By comparing the hemodynamic response associated with perception and recall, both with and without consciousness, functional imaging studies have begun to identify regions of the brain correlated with consciousness.

Imaging Perception with and Without Consciousness

Mapping of brain function began in the middle of the 19th century, fully 100 years before the advent of functional imaging of the brain. By correlating cognitive performance with the anatomical location of brain lesions, neurologists identified brain regions involved in specific cognitive functions (see Chapter 1). However, this approach has a number of important limitations that prevented many questions about function from being answered.

For example, just because an area of primary sensory cortex may be necessary for conscious perception, because it is involved in the initial processing of sensory information, does not mean it is responsible for the conscious experience. It may simply relay sensory information to higher-order cortex that is responsible for consciousness. In principle, functional imaging can help make these distinctions.

Indeed, neural correlates of conscious perception can be measured experimentally using visual illusions in which the percept is dissociated from the physical stimulus. One such illusion results from binocular rivalry, which occurs when different visual stimuli are presented simultaneously to each eye. Typically, awareness of one or the other stimulus is suppressed so that we are consciously aware of one stimulus at a time, never both. Thus one eye's view dominates consciousness for several seconds, only to be replaced by the other eye's view. What makes binocular rivalry so remarkable is that the perceptual experience fluctuates while the physical stimulus remains constant. Because of this dissociation, binocular rivalry presents a unique opportunity for studying the neural correlates of consciousness.

What systems are recruited when one eye's view becomes dominant? According to one idea, neurons in the early stages in visual processing respond to the physical stimulus of each eye, but in later stages the signals from these neurons are switched on and off, causing the perceptual alternations. That is, a later stage serves as a "gate" to visual consciousness.

Does such a gate exist? If so, what neurons in the brain have this gating function? Are the neurons localized in particular brain areas? Are they a particular cell type? Does the gating occur through modulation of the cells' firing rates or some other component of their responses (eg, spike timing, synchronous firing)? What are the neural circuits and neural computations that support the competition between the two stimuli?

Although we do not yet have firm answers to these questions, the evoked metabolic activity of the brain under conditions of binocular rivalry has been measured with fMRI. One fMRI experiment capitalized on an interesting aspect of this perceptual phenomenon; during an alternation one typically perceives a traveling wave in which one pattern emerges initially at one location and expands progressively as it renders the other pattern invisible. The physical stimulus does not change while this conscious perceptual change is taking place—it is all "in your brain." This experiment established that waves of activity in primary visual cortex (V1) accompanied the perceptual changes during binocular rivalry.

Because the primary visual cortex is topographically organized—adjacent neurons respond to adjacent locations in the visual field (see Chapter 27)—it was possible to show that neural activity propagated over subregions of primary visual cortex. The sequential activation of these subregions correlated with the dynamic perceptual changes experienced during binocular rivalry (Figure 20–6). Similar waves of activity propagated over the immediately adjacent secondary visual areas (V2 and V3).

Box 20-4 Diffusion Tensor Imaging

Diffusion tensor imaging (DTI) is another application of MRI, complementary to fMRI, for visualizing anatomical properties of the brain. DTI begins with measurements of how far water diffuses within the brain. The random displacements of molecules resulting from thermal agitation (Brownian motion) obey a statistical law that was described by Einstein in 1905.

In a homogeneous medium the average distance moved by the molecules increases linearly with the square root of time. For water at body temperature, 68% of the molecules will have moved less than $17~\mu m$ during 50 ms. Water diffusion in the presence of large molecules or cell membranes is impeded.

It has been known for decades that MRI can be used to measure differences in the extent of water diffusion, called diffusion MRI, that depend on brain anatomy. One of the most successful clinical applications of diffusion MRI has been in the management of stroke. Michael Moseley discovered in 1990 that water diffusion decreases considerably in ischemic brain tissue within minutes of a restriction in blood flow. Diffusion MRI has since become a standard diagnostic procedure for the evaluation and management of stroke patients.

Peter Basser realized in 1994 that MRI could be used to characterize the anisotropy of water diffusion (differences in diffusion in different directions), which led to the development of DTI. DTI can be used to characterize the local orientation of the fiber bundles at each location in the white matter of the brain. This is because white matter is made up of bundles of axons (fascicles), and diffusion of water is approximately three to six times faster in the direction of the white matter fiber bundles than in the perpendicular direction.

A DTI measurement begins like all MRI measurements, by placing the subject in a strong magnetic field. A radio frequency pulse is applied so that the water protons wobble in phase with one another (see Box 20–3). Next a gradient in the magnetic field is introduced along one axis for a brief period of time. Let's assume for the moment that this gradient is initially applied in the rostral-caudal direction so that the magnetic field is stronger at the front of the brain than at the back of the brain; but we will see that each of several gradient directions will be used in sequence.

Because of the gradient, the rate of precession is faster for the water protons in the front of the brain than for those in the back of the brain. Indeed, the rate is slightly faster for the water protons at the front of each voxel than for those at the back of each voxel. When the gradient is turned off, therefore, the water protons dephase, each by a fixed amount depending on its front-back location.

A reversed gradient is then introduced with the same amplitude and duration but with the opposite direction (caudal-rostral in this example). If nothing has moved in the front-back direction, then this reversed gradient will perfectly rephase all of the water protons so that they are once again precessing in perfect synchrony.

Because of diffusion, however, each of the water molecules will have moved by some amount during the time period between the first gradient application and the reversed gradient. If diffusion (in the front-back direction) is less in one voxel than in another, the result will be better resynchronization and a brighter MRI image intensity in the voxel with less diffusion. For this example with rostral and caudal gradients, diffusion only in the front-back direction matters. If a water molecule diffuses rightward or leftward, then the dephasing and rephasing caused by the two gradients will perfectly cancel.

The measurement is repeated for each of several directions to characterize the diffusion anisotropy. A separate image of the brain is reconstructed for each direction. A voxel in white matter will typically exhibit greater diffusion in the direction of the fiber tract (dimmer image intensity in the corresponding image) and less diffusion in the other directions (brighter image intensities). These separate images can then be combined to show the degree of anisotropy and the dominant direction of anisotropy (Figure 20–5A).

The most advanced application of DTI is fiber tracking, the only noninvasive method currently available to characterize anatomical connectivity in the living human brain. Fiber tracking is a computational analysis of the DTI measurements, the basic idea of which is to follow the path of anisotropy (and hence the fiber track) from one location in the brain to another (Figure 20–5B).

There are, however, important limitations to the accuracy and precision with which fiber tracking can be done with DTI. Unlike the use of retro- and anterograde tracers that label connections established by individual axons, DTI reflects the statistical average of axon trajectories through each voxel of white matter tissue.

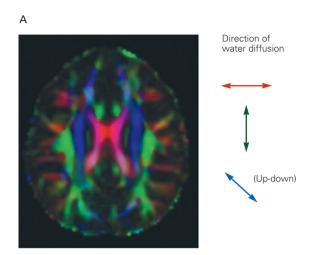

Figure 20–5A MRI measurement of diffusion anisotropy. Water diffusion in white matter is anisotropic, and the anisotropy can be measured with MRI. The color and brightness at each location in the image represents the diffusion of a small volume (or voxel) of tissue. Brightness corresponds to the degree of diffusion anisotropy. White matter mostly appears bright (diffusion is highly anisotropic), whereas gray matter and ventricles are dark (isotropic diffusion). Colors represent the dominant orientation of white matter fibers: red indicates that diffusion is greatest in the right–left direction, green indicates diffusion is greatest in the front–back direction, and blue indicates diffusion is greatest in the up–down direction. (Reproduced, with permission, from Ben-Shachar, Dougherty, and Wandall 2007.)

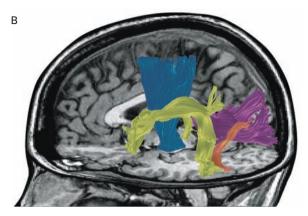

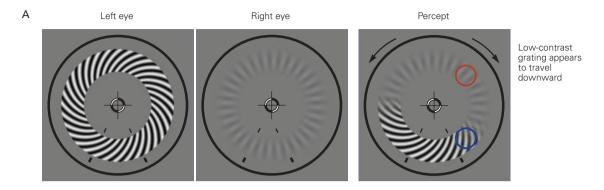

Figure 20-5B White matter fiber tracts reconstructed from DTI. Each "virtual fiber bundle" was computed from the DTI measurements by starting at one location in the brain and following the path of greatest anisotropy. Depicted are four fiber tracts that are believed to be important for reading. Yellow fibers are the superior longitudinal fasciculus that connects temporoparietal cortex (including Wernicke's area, which is critical for language comprehension) with lateral frontal cortex (including Broca's area, implicated in language production). The purple fibers are passing through the corpus callosum connecting regions of the two occipital lobes and regions of the two temporal lobes. Blue fibers are corona radiata fibers that pass through the posterior limb of the internal capsule. Finally, the orange fibers connect the posterior occipitotemporal cortex (including a region believed to be critical for letter recognition) with the lateral cortical surface at the border between the occipital and temporal lobes.

Specifically, the intensity in each voxel of each diffusion MRI image depends on the average diffusion of all of the water molecules within that voxel.

Hence, only white matter bundles composed of large numbers of axons are visible (current methods fail to detect tracts smaller than 5 mm in cross-section diameter). The many thin tendrils of white matter connecting nearby cortical areas are not reliably detectable, nor are intracortical connections that remain entirely within gray matter.

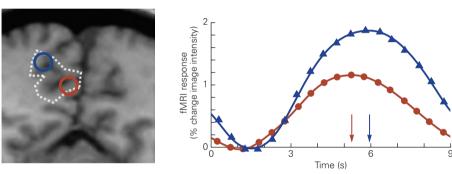

In some white matter regions fiber tracking is difficult because different fiber bundles cross, so there is no single dominant diffusion direction. In other regions different fiber bundles travel together over some distance and then separate, which can cause fiber tracking software to make errors.

Even so, DTI is being used in conjunction with fMRI to characterize the normal development of human brain connectivity, and to identify subtle anomalies in brain function and connectivity in a variety of neurological diseases (eg, multiple sclerosis, Alzheimer disease), developmental disabilities (eg, dyslexia), and mental illnesses (eg, schizophrenia).

Waves of neural activity pass through V1 regions

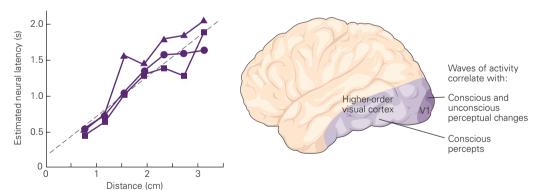

Figure 20–6 Neural correlates of conscious visual perception. (Reproduced, with permission, from Lee, Blake, and Heeger 2005.)

A. A subject is presented with a high-contrast spiral grating in the left eye and a low-contrast radial grating in the right, and each image is restricted to an annular region of the visual field. The subject perceives a traveling wave in which the low-contrast pattern is seen to spread around the annulus, starting at the top and progressively erasing the other image from awareness. (See part B for the explanation of the red and blue circles.)

B. An anatomical image cut through the posterior occipital lobe, perpendicular to the calcarine sulcus. The **red circle** identifies a subregion of primary visual cortex where cells represent

the upper-right quadrant of the annular region of the visual field (depicted in part A). The **blue circle** identifies a subregion where cells represent the lower-right quadrant. The plot compares the fMRI measurements from these two subregions. Red and blue curves correspond to the red and blue outlined subregions; **arrows** indicate when these curves peak. The blue curve is delayed in time and larger in amplitude, as the high-contrast pattern remained visible for a longer period of time.

C. Propagation speed of the underlying neural activity, computed from the fMRI measurements of three subjects. Temporal latency of the neural activity is plotted as a function of cortical distance measured along the folded surface of the cerebral cortex. The dashed slope corresponds to a propagation speed of approximately 2 cm/s across the cortical surface.

Another experiment showed, however, that the activity waves in primary visual cortex are not themselves sufficient for conscious perception. In this experiment subjects were temporarily distracted (their attention was diverted) so that they did not perceive the rival stimulus patterns presented to the two eyes. Waves of activity were still clearly evident in primary visual cortex, even though subjects did not experience a corresponding traveling wave. However, waves of activity were not evident in V2 and V3.

Indeed, activity in a number of brain areas other than the primary visual cortex correlates with the perceptual alternations of binocular rivalry, including higher-order visual areas in the inferior temporal lobe and areas in parietal and prefrontal cortex. It is likely that these different higher-order cortical areas play distinctive roles in visual perception during binocular rivalry. Attention, mediated by feedback from areas in parietal and prefrontal cortex, is thought to play a crucial role in coordinating the activity across these brain areas to yield conscious perceptual states, as discussed in a later section.

Perceptions are typically made up of multiple sensations, not just a single sensation isolated in experimental conditions. An introduction to a person, for example, involves visual, auditory, and often somatosensory and olfactory information, so that the conscious experience likely reflects activity in several higher-order sensory cortices. Although a multimodal percept arises from activity in numerous brain regions, we sense the conscious experience as a unified, seamless whole. The linkage between discrete functional systems in the brain that gives rise to a unified experience of consciousness is sometimes called the "binding problem." According to one view, a conscious experience occurs when neural activity in disparate regions of the brain is time locked: The activity in these areas becomes temporarily synchronous.

Imaging Memory with and Without Consciousness

Conscious perception and conscious memories have long been linked. According to one view, conscious recall occurs when a stimulus reactivates the brain regions that first encoded the conscious percept being remembered. An fMRI experiment by Randy Buckner and colleagues provided the first empirical evidence in support of this idea.

Buckner trained subjects to associate pictures or sounds with a written word. For example, the word "dog" was associated either with a picture of a dog or the sound of a dog barking. Subjects were scanned with fMRI after they were shown the word

and asked to recall the associated picture or sound, thereby mapping memory-storage regions. In addition, they were scanned during exposure to the picture or sound, thereby mapping regions involved in perception.

Remarkably, first hearing and later recalling a sound stimulated some of the same higher-order regions in the auditory cortex, and viewing and later recalling a picture stimulated some of the same higher-order regions in the visual cortex. However, conscious recall of sounds or pictures did not activate areas of primary sensory cortex. These results provide evidence that conscious memory recall used some of the same regions of the brain that were used for conscious perception.

The notion that higher-order sensory cortex is recruited for memory is reinforced by studies of different stages of sleep. Although dreams are not faithful recollections of the external world, they are remarkably vivid, comparable to conscious memory. Functional imaging studies of rapid-eye-movement sleep, during which dreaming occurs, and slowwave sleep, characterized by the absence of dreams, have found that dreaming is associated with activity throughout higher-order sensory cortical areas. Just as in Buckner's experiment, primary sensory cortex is not activated during dreaming.

Other imaging studies have found that when a stimulus induces only a sense of familiarity, not a full-blown recollection, brain activity tends to be confined to specific sensory regions representing one, or at most, a very few modalities. Taken together these studies demonstrate that, just as with conscious perception, simultaneous activity in several higher-order sensory regions underlies recollection (conscious recall of the stimulus along with the associated details of the context, when and where the stimulus was initially perceived, what else happened at the same time, etc.).

Imaging Attentional Modulation of Conscious Perception

Our brain is constantly bombarded by external and internal stimulation, yet at any given moment we are only aware of a small fraction of this input. Attention is one factor that influences the focus and scope of our awareness. As we mentioned earlier in Chapter 17, the American psychologist William James defined attention as ". . . the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneous possible objects or trains of thought." James captured the key element of attention—when

confronted with more than one input the brain does not process all inputs equally.

Performance on a wide variety of perceptual discrimination and identification tasks is faster and more accurate when subjects attend to the right place at the right time. Several investigators have developed experimental protocols to characterize the behavioral consequences of attention. For example, in a visual attention experiment the subject is asked to fixate a spot at the center of a computer screen while visual stimuli are shown on either side. The subject is instructed to shift attention to one side of the screen, without moving the eyes, when a visual cue, such as an arrow, indicates an upcoming stimulus at the side of the screen. Behavioral performance (speed or accuracy) in a visual discrimination task is enhanced when subjects shift their attention to the side of the screen containing the stimulus.

On the basis of studies of patients with attention deficits as a consequence of a neglect syndrome following a stroke, the parietal and frontal lobes have long been implicated in the control of visual attention (Chapter 17). Using PET imaging, Michael Posner and his colleagues have confirmed that frontal and parietal lobe regions contribute to the control of attention. Similarly, as we saw in Chapter 17, electrophysiological studies of attention by Michael Goldberg have identified neurons in areas of the parietal lobe that respond more strongly to attended stimuli than to unattended stimuli.

William James described two different kinds of attention. One is passive, automatic, stimulus-driven, and transient, whereas the other is active, voluntary, conceptually driven, and sustained. In "passive immediate sensorial attention the stimulus is a sense-impression, either very intense, voluminous, or sudden . . . big things, bright things, moving things . . . blood." We now refer to passive, nonvoluntary attention as exogenous attention, whereas active and voluntary attention is called endogenous attention.

Functional imaging has revealed that the two types of attention recruit different subregions of the brain. During voluntary attention certain parietal areas (within the intraparietal sulcus) and frontal areas (frontal eye fields) are active when subjects are instructed to shift or maintain attention. Shifts in attention are mediated by transient responses in the frontal and parietal regions immediately following the presentation of a cue. The maintenance of attention, critical for our ability to focus on a particular location in the visual field over an extended period of time, is mediated by sustained activity in the visual cortex as well as some of the same parietal and frontal brain regions. Additional brain areas become active when attention is diverted by a particularly significant or unexpected stimulus. For

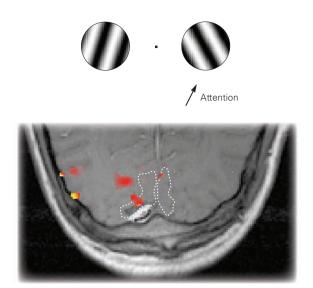

Figure 20–7 Neural correlate of attention. Subjects had to fixate on the center of a display (above) and were instructed to attend to one side or the other without moving their eyes. Here an axial (horizontal) slice through the occipital lobe of the brain (below) shows functional activity (red and orange) superimposed on the brain anatomy. The dashed outlines mark the boundaries of primary visual cortex. Activity in the left hemisphere increased when the subject attended to the right and vice versa (stimuli on the right are processed by neurons in the left hemisphere and vice versa). (Adapted, with permission, from Gandhi, Heeger, and Boynton 1999.)

example, the amygdala is involved in diverting attention to emotionally salient (particularly fearful) stimuli such as a fearful face or a snake (see Chapter 48).

Attention is believed to be controlled by a particular network of cortical and subcortical areas. But how does this give rise to the improved behavioral performance discussed above? One idea is that signals from higher-order cortical areas flow back down to sensory cortical areas to facilitate the sensory representation of an attended stimulus. Functional imaging experiments have found that in this way the neural representation of an attended stimulus is amplified. This amplification is correlated with, and is believed to cause, the improvements in behavioral performance that accompany attention (Figure 20–7).

Functional Imaging Has Limitations

Despite its remarkable abilities, functional imaging, like any tool, has some technical and conceptual limitations. Four variables that correlate with brain metabolism can be used in functional imaging: glucose

uptake, cerebral blood flow, cerebral blood volume, and deoxyhemoglobin content. The latter is the basis of the BOLD response on which most fMRI measurements are based (see Box 20–3).

Deoxyhemoglobin content is the only one that cannot be measured in absolute terms and is in fact dependent on a complex and poorly understood interplay among cerebral blood flow, cerebral blood volume, and the basal (or "resting") state of the brain region under investigation. Two brain regions with differing basal states, therefore, may lead to different BOLD responses, even if a stimulus induces identical changes in oxygen metabolism in each region.

Thus, inferring that differences in the BOLD response necessarily reflect underlying differences in oxygen metabolism and neural activity can lead to false conclusions. For example, the amplitude of the BOLD response to visual stimuli measured in the primary visual cortex is typically larger than the BOLD response to motor stimuli measured in the primary motor cortex. One might conclude that the visual cortex is metabolically more responsive then the motor cortex, but this difference between the regions is more likely to reflect differences in basal deoxyhemoglobin. The BOLD response, therefore, can be similar in several areas of the brain stimulated by a particular stimulus, but this similarity cannot tell us which area of the brain is more metabolically active than another.

Moreover, because most disorders of the brain affect the basal state and deoxyhemoglobin of targeted brain regions, similar false conclusions might be drawn when comparing the BOLD responses of patients and healthy controls (Figure 20–8). This limitation has hampered the usefulness of BOLD fMRI in clinical populations but can be overcome by calibrating BOLD measurements. Moreover, new functional MRI techniques measure cerebral blood flow or cerebral blood volume in absolute terms.

What component of neuronal activity is most highly correlated with these measures of brain metabolism? Although it is known that the BOLD response (and the other functional imaging measures) is triggered by metabolic demands of increased neural activity, the details of this process are poorly understood. Considerable evidence suggests that increased blood flow follows from increased synaptic activity. Thus, fMRI responses may be most closely related to synaptic input and intracortical processing within a cortical area, not the spiking output, and there are some clear demonstrations that change in blood flow can be dissociated from spiking activity.

Cortical circuits are, however, dominated by massive local connectivity; most synaptic inputs originate from nearby neurons, while only a small minority originates from distant sites such as the thalamus or other cortical areas. Thus, synaptic inputs in the cerebral cortex are produced mostly by neighboring neurons, leading typically to a tight coupling of synaptic and spiking activity, as well as metabolic responses (including BOLD fMRI). It is not surprising, therefore, that fMRI responses have often been found to be highly correlated with neural spiking. The extent of decoupling of

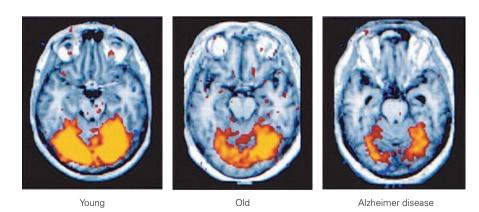

Figure 20–8 A potential pitfall of functional magnetic resonance imaging. Deoxyhemoglobin content, which is the basis for blood oxygen level dependent (BOLD) fMRI, is the result of a complex interplay between blood flow, blood volume, and oxygen metabolism. For this reason it is a correlate of brain metabolism for which absolute measurements cannot be made. Imaging deoxyhemoglobin content, therefore, must be

interpreted with caution. For example, as shown here, a simple visual stimulation experiment results in different BOLD signals in the visual cortex of young, old, and Alzheimer subjects with no apparent visual defects. These results may reflect differences in vascular physiology associated with aging and disease more than underlying differences in brain function. (Adapted, with permission, from Buckner et al. 2000.)

Box 20–5 Limitations of Functional Imaging

Another potential pitfall with functional imaging is the logic by which the results are interpreted. Research using functional imaging often begins by hypothesizing that a particular cognitive process occurs in a functionally specialized brain area. An experiment is then designed with two or more stimuli or tasks that differ in the demands they make on the hypothesized cognitive process. If there is such a cognitive process and if it is functionally localized in the brain, then the particular brain area would be expected to become more active with increased demand on that cognitive process.

If the brain region of interest is activated during the experiment, one is tempted to conclude that the hypothesis has been confirmed. This kind of reasoning is flawed and has led to a latter-day phrenology in which every bump in brain anatomy is assigned a function.

If subjects are asked to view two or more different stimuli or perform two or more different tasks, the brain will certainly respond differently to the different stimuli or different tasks. If no difference in brain activity is shown in the experiment, it may be because of a failure in the measurement technique (eg, insufficient spatial or temporal resolution, too much noise or artifact in the measurements, etc.).

In fact, finding a difference in brain activity merely confirms that the participant experienced two or more different stimuli or performed two or more different tasks. This one experiment cannot confirm or disprove that some cognitive process is localized in one area of the brain, but it may be a worthwhile starting point for further research. Further experiments can determine if the activity in the brain area changes systematically with parallel cellular–physiological studies of the homologous area in monkeys or with theoretical predictions based on a computational model of the hypothesized cognitive process.

It is also important to rule out alternative theories. Showing a correlation with the predictions of a theory provides only weak evidence in support of that theory. Showing a positive correlation with the predictions of one theory and negative correlations with the predictions of alternative hypotheses provides much stronger support.

synaptic and spiking activity depends on the nature of the cortical circuits, that is, whether the cortical activity is dominated by the local recurrent circuitry or by synaptic inputs (either feedforward or feedback) from other brain areas. Functional MRI measurements may be highly correlated with the spiking activity of a brain area under some circumstances, but with subthreshold modulatory input under other circumstances. One implication of this is that fMRI measurements must be interpreted with caution (Box 20–5).

An Overall View

Functional imaging provides a key bridge between behavioral studies of human cognition and electrophysiologic studies of neural function in intact experimental animals such as monkeys or genetically modified mice. Insofar as cognition emerges from a complex interplay across many regions of the brain, the ability to record brain activity simultaneously from multiple areas endows functional imaging with unique exploratory powers.

Functional imaging is expanding on three fronts. First, although it is clear that functional imaging can record meaningful signals from the brain at work, it is also clear that we do not yet have a complete understanding of what is causing these changes in signal, how they are generated, and what they are precisely telling us about underlying neural processes. Achieving a full understanding will require coupling functional imaging with invasive techniques. Accordingly, one of the important developments in the field is in the use of monkeys and transgenically engineered mice to investigate the physiological and molecular mechanisms underlying functional imaging.

Second, functional imaging studies are moving beyond establishing a catalog of the component parts of cognition toward an understanding of how the parts interact within large-scale networks. For example, investigators are beginning to explore how higherand lower-order sensory areas interact with the medial temporal lobes and the parietal and prefrontal cortex to give rise to cognition or consciousness.

Third, studies are scaling down from the largescale analysis of the whole brain to a more focused investigation of discrete brain areas, such as the numerous visual cortical areas, the olfactory bulb, and the hippocampal formation. These studies are designed not for human brain mapping but rather to test computational theories of the function and functional organization of predefined brain areas.

Detail of a self-portrait by Chuck Close. Viewed from a short distance, this painting appears to be an abstract grid of vividly colored squares and ovals. But, when viewed from farther away, the local colors blend and we begin to perceive a spectacle-framed eye. The interplay between these local and global features, which are conveyed by discrete visual pathways, gives the portrait its particular dynamism.

Chuck Close has prosopagnosia, or difficulty in recognizing faces; his technique of flattening and subdividing an image into manageable elements enhances his ability to both perceive and portray the face. The complete painting is shown above. V

Perception

... one day in winter, on my return home, my mother, seeing that I was cold, offered me some tea, a thing I did not ordinarily take. I declined at first, and then, for no particular reason, changed my mind. She sent for one of these squat, plump little cakes called "petites madeleines," which look as though they had been moulded in the fluted valve of a scallop shell. And soon, mechanically, dispirited after a dreary day with the prospect of a dreary morrow, I raised to my lips a spoonful of the tea in which I had soaked a morsel of the cake. No sooner had the warm liquid mixed with the crumbs touched my palate than a shudder ran through me and I stopped, intent upon the extraordinary thing that was happening to me. An exquisite pleasure had invaded my senses, something isolated, detached, with no suggestion of its origin. And at once the vicissitudes of life had become indifferent to me, its disasters innocuous, its brevity illusory—this new sensation having had on me the effect which love has of filling me with a precious essence; or rather this essence was not in me, it was me.*

THE TASTE OF THE MADELEINE dipped in tea is one of the most famous evocations of sensory experience in literature. Proust's description of the conscious nature of sensation and memory provides profound insights into some of the subjects that we shall explore in the next few chapters. His description of the shape of the pastries on the plate, the warmth of the tea, and the mingled flavors of tea and cake remind us that knowledge of the world arises through the senses.

Perceptions begin in receptor cells that are sensitive to one or another kind of stimulus energy. Most sensations are identified with a particular type of stimulus. Thus, light of short wavelength falling on the eye is seen as blue, and sugar on the tongue tastes sweet. How the quantitative aspects of physical stimuli correlate with the sensations they evoke is the subject of psychophysics. Additional information about perception can be obtained from studying the various sensory receptors and the stimuli to which they respond as well as the sensory pathways that carry information from these receptors to the cerebral cortex. Specific cells in the sensory system, both peripheral receptors and central neurons, encode certain critical attributes of sensations, such as location and intensity. Other attributes of sensation are represented by the pattern of activity in a population of sensory neurons. We know, for example, that taste depends greatly

^{*}Proust, M. [1913] 1981. Remembrance of Things Past. Volume 1: Swann's Way: Within a Budding Grove. Pléiad edition translated by C.K. Scott Moncrieff and Terence Kilmartin. New York: Vintage. p. 48.

on receptor specificity. In contrast, the differentiation of sounds depends in large part on pattern coding. Determining the extent to which receptor specificity and patterns of neural activity are used in different sensory systems to encode information is a major task of current research in sensory physiology.

Each sensory modality is mediated by a distinct neural system with multiple components that contribute to perception. Sensory pathways include neurons that link the receptors at the periphery with the spinal cord, brain stem, thalamus, and cerebral cortex. The perception of a touch on the hand begins when cutaneous mechanoreceptors cause a population of afferent fibers to discharge action potentials, thus setting up a propagated response in the dorsal column nuclei and then in the thalamus. From the thalamus sensory information flows to several areas of the cerebral cortex, each of which analyzes particular aspects of the original stimulus. This cortical representation is closely correlated with our conscious perception. For example, an illusion of sensation in the hand, albeit a slightly blunted one, can be elicited by electrical stimulation of the cortical area that represents the hand.

In this part of the book, we examine the principles essential for understanding how perception occurs in the brain. Contrary to our intuitive understanding based on personal experience, perceptions are not direct copies of the world around us. The information available to sensory systems at any instant in time is imperfect and incomplete. So perceptual systems are not built like physical devices for making measurements, but instead are built to perform inferences about the world. Sensory data should not be thought of as giving answers, but as providing clues.

The brain, for example, is where seeing happens; it is the brain that figures out what the clues mean. Thus visual perception is a creation of the brain. It is based on the input extracted from the retinal image. But what is seen in the "mind's eye" goes far beyond what is presented in the input. The brain uses information it has extracted previously as the basis for educated guesses—perceptual inferences about the state of the world.

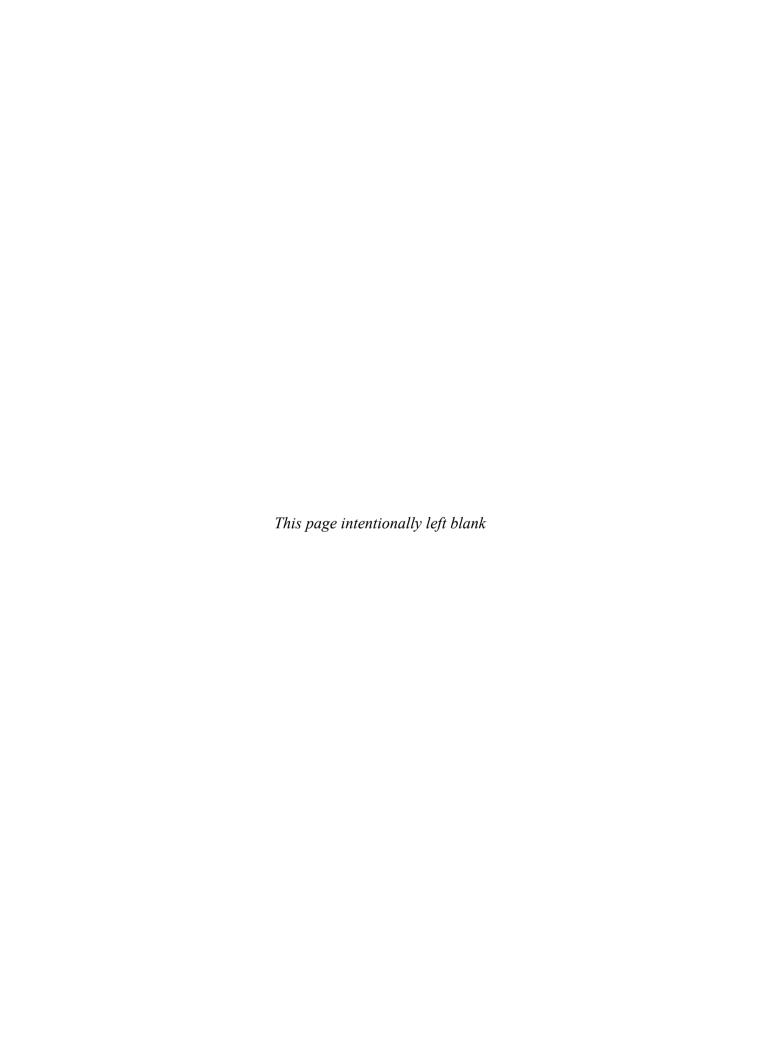

Sensory systems contain many representations that each specialize in different kinds of sensory information processing. Throughout each sensory system, from the peripheral receptors to the cerebral cortex, information about physical stimuli is transformed in stages according to computational rules that reflect the functional properties of the neurons and their interconnections at each stage.

The visual system, for example, transforms the stimulus energy that the retinal receptors receive into a neural code of action potentials like the dots and dashes of a Morse code. The brain solves the problem of computation by performing relatively simple operations in parallel in massive numbers of neurons, and by repeating these operations at multiple hierarchical stages. The great mystery of vision is how we respond to trains of action potentials in different neurons of the visual system by seeing an image—like a face.

A major goal of cognitive neural science is to determine how the information that reaches the cerebral cortex by means of parallel afferent pathways is bound together to form a unified conscious perception. Indeed, one of the hopes driving cognitive neural science is that progress in understanding the binding problem will yield our first insights into the biological basis of attention and ultimately consciousness.

An Overall View

Since Ancient times Humans have been fascinated by the nature of sensory experience. The Greek philosopher Aristotle defined five senses—vision,

hearing, touch, taste, and smell—each linked to specific sense organs in the body: the eyes, ears, skin, tongue, and nose (Figure 21–1). Pain was not considered to be a specific sensory modality but rather an affliction of the soul. Intuition, often referred to colloquially as a "sixth sense," was something beyond the experience of classic sensory systems. Today neurobiologists are more likely to describe intuition as inferences derived from previous experience and thus the result of cognitive rather than sensory processes.

In this chapter we consider the organizational principles and coding mechanisms universal to all sensory systems. We define *sensory* information as neural activity originating from stimulation of receptor cells in specific parts of the body. These senses include the classic five senses plus a variety of modalities not recognized by the ancients but essential to bodily function: the *somatic* sensations of proprioception (posture and movement of our own body), pain, itch, and temperature; *visceral* sensations (both conscious and unconscious) necessary for homeostasis; and the *vestibular* senses of balance (the position of the body in the gravitational field) and head movement.

The extent to which features of sensory processing have been conserved in the course of human evolution seems nothing short of astonishing. In each of the sensory systems receptors provide the first neural representation of the external world. This information flows centrally to regions of the brain involved in cognition. The sensory pathways have both serial and parallel components, consisting of fiber tracts with thousands or millions of axons interrupted by synaptic relays comprising millions of neurons. Along the way information is transformed from relatively simple forms to

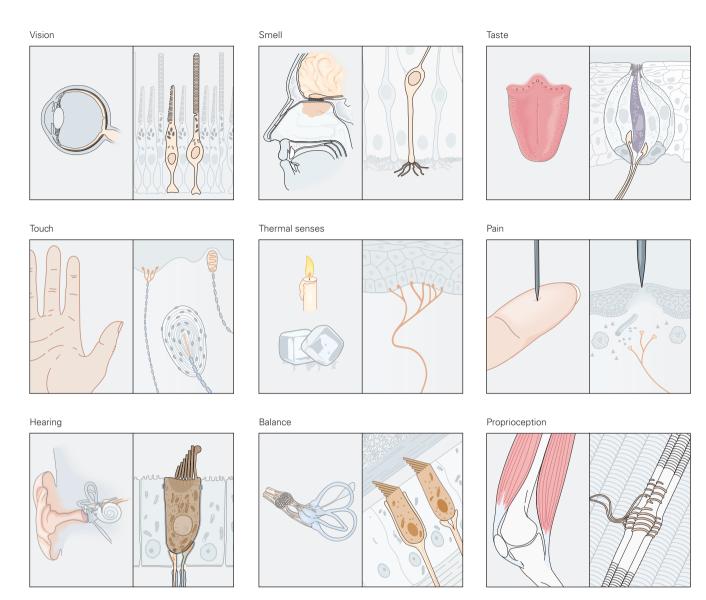

Figure 21–1 The major sensory modalities in humans are mediated by distinct classes of receptor neurons located in specific sense organs. Each class of receptor cell transforms one type of stimulus energy into electrical signals that are encoded as trains of action potentials. The principal receptor cells include photoreceptors (vision), chemoreceptors (smell, taste, and pain), thermal receptors, and mechanoreceptors

(touch, hearing, balance, and proprioception). The classic five senses—vision, smell, taste, touch, and hearing—and the sense of balance are mediated by receptors in the eye, nose, mouth, skin, and inner ear, respectively. The other somatosensory modalities—thermal senses, pain, and proprioception—are mediated by receptors distributed throughout the body.

the complex forms that are the basis of cognition. Sensory pathways are also recursive. The higher centers in the brain modify and structure the incoming flow of sensory signals by feeding information back to earlier stages of processing; thus percepts are shaped by internal as well as environmental factors.

In each sensory modality a specific type of stimulus energy is transformed into electrical signals by specialized receptors. The sensory information is transmitted to the central nervous system by trains of action potentials that represent particular aspects of the stimulus. The question that has intrigued philosophers and scientists alike is whether experienced sensations accurately reflect the stimuli that produce them or whether our knowledge of the world is inherently subjective and imprecise.

Modern thought about how knowledge is represented in the brain began with European philosophers of the 17th, 18th, and 19th centuries whose interest in sensation and perception was related to the question of human nature itself. The major division was between the empiricists, represented by John Locke, George Berkeley, and David Hume, and the idealists, including René Descartes, Immanuel Kant, and Georg Wilhelm Friedrich Hegel. Locke, the preeminent empiricist, advanced the idea that the mind at birth is a blank slate, or tabula rasa, void of any ideas. Knowledge is obtained through sensory experience—what we see, hear, feel, taste, and smell. In fact, Berkeley questioned whether there was any sensory reality beyond the experiences and knowledge acquired through the senses. He asked the now-famous question: Does a falling tree make a sound if no one is near enough to hear it?

The idealists responded that the human mind possesses certain innate abilities, including logical reasoning itself. The 18th-century German philosopher Immanuel Kant classified the five senses as categories of human understanding. He argued that perceptions were not direct records of the world around us but rather were products of the brain and thus depended on the architecture of the nervous system. Kant referred to these brain properties as *a priori* knowledge.

Thus in Kant's view the mind was not the passive receiver of sense impressions envisaged by the empiricists. Rather the human mind had evolved to conform to certain universal conditions such as space, time, and causality. These conditions were independent of any physical stimuli detected by the body. For Kant and the idealists this meant that knowledge is based not only on sensory stimulation but also on the brain's properties that organize sensory experience. If sensory experience is inherently subjective and personal, they said, it may not be subject to scientific analysis.

Psychophysics Relates the Physical Properties of Stimuli to Sensations

The modern study of sensation and perception began in the 19th century with the emergence of experimental psychology as a scientific discipline. The first psychologists—Ernst Weber, Gustav Fechner, Hermann Helmholtz, and Wilhelm Wundt—focused their experimental study of mental processes on sensation, which they believed was the key to understanding the mind. Their findings gave rise to the fields of psychophysics and sensory physiology.

Psychophysics describes the relationship between the physical characteristics of a stimulus and the attributes

of the sensory experience. Sensory physiology examines the neural consequences of a stimulus—how the stimulus is transduced by sensory receptors and processed in the brain. Some of the most exciting advances in our understanding of perception have come from merging these two approaches in both human and animal studies. For example, functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) have been used in controlled experiments to identify regions of the human brain involved in the perception of pain.

Psychophysical Laws Govern the Perception of Stimulus Intensity

Early scientific studies of the mind focused not on the perception of complex qualities such as color or taste but on phenomena that could be isolated and measured precisely: the size, shape, amplitude, velocity, and timing of stimuli. Weber and Fechner developed simple experimental paradigms to study how and under what conditions humans are able to distinguish between two stimuli of different amplitudes. They quantified the intensity of sensations in the form of mathematical laws that allowed them to predict the relationship between stimulus magnitude and sensory discrimination.

For example, in 1834 Weber demonstrated that the sensitivity of a sensory system to differences in intensity depends on the absolute strength of the stimuli. We easily perceive that 1 kg is different from 2 kg, but it is difficult to distinguish 50 kg from 51 kg. Yet both sets differ by 1 kg. This relationship is expressed in the equation now known as Weber's law:

$$\Delta S = K \cdot S$$

where ΔS is the minimal difference in strength between a reference stimulus S and a second stimulus that can be discriminated, and K is a constant. This is termed the *just noticeable difference* or difference limen. It follows that the difference in magnitude necessary to discriminate between a reference stimulus and a second stimulus increases with the strength of the reference stimulus.

Fechner extended Weber's law to describe the relationship between the stimulus strength (*S*) and the intensity of the sensation (*I*) experienced by a subject:

$$I = K \log(S/S_0)$$

where S_0 is the threshold amplitude of the stimulus and K is a constant. Although Fechner's law was widely accepted for nearly a century after its publication in 1860, his assumption that the intensity of

sensation could be equated with the sum of equal increments in "just noticeable differences" turned out to be incorrect.

In 1953 S. S. Stevens demonstrated that, over an extended range of stimulation, subjective experience of sensation intensity is best described by a power function rather than by a logarithmic relationship. Stevens' law states that:

$$I = K(S - S_0)^n$$

For some sensory experiences, such as the sense of pressure on the hand, the relationship between the stimulus magnitude and the perceived intensity is linear, that is, a power function with a unity exponent (n = 1).

The lowest stimulus strength a subject can detect is termed the *sensory threshold*. Thresholds are normally determined statistically by presenting a subject with a series of stimuli of random amplitude. The percentage of times the subject reports detecting the stimulus is plotted as a function of stimulus amplitude, forming a relation called the *psychometric function* (Figure 21–2). By convention, threshold is defined as the stimulus amplitude detected in half of the trials. Thresholds can also be determined by the method of limits, in which the subject reports the intensity at which a progressively decreasing stimulus is no longer detectable or an increasing

stimulus is detectable. This technique is widely used in audiology to measure hearing thresholds.

The measurement of sensory thresholds is a useful diagnostic technique for determining sensory function in individual modalities. An elevated threshold may signal an abnormality in sensory receptors (such as loss of hair cells in the inner ear caused by aging or exposure to very loud noise), deficits in nerve conduction properties (as in multiple sclerosis), or a lesion in sensory-processing areas of the brain. Sensory thresholds may also be altered by emotional or psychological factors related to the conditions in which stimulus detection is measured.

Psychophysical Measurements of Sensation Magnitude Employ Standardized Protocols

The lasting importance of Fechner's work was the development of formal quantitative methods for measuring sensory performance and mathematical techniques to analyze them. Three of his methods are still widely used, either exactly as he formulated them or in a modified form: (1) the method of constant stimuli, in which a fixed set of stimuli is presented repeatedly to obtain a statistical characterization of the behavior associated with each stimulus; (2) the method of limits,

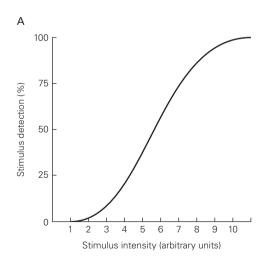

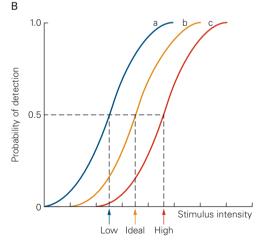

Figure 21–2 The psychometric function defines the mathematical relationship between the amplitude of a stimulus and the intensity of the sensation felt by the subject.

A. The psychometric function plots the percentage of stimuli detected by a human observer as a function of the stimulus magnitude. Threshold is defined as the stimulus intensity detected on 50% of the trials. Psychometric functions are also used to measure the just noticeable difference between stimuli that differ in intensity, frequency, or other parametric properties.

B. Detection and discrimination thresholds depend on the criteria used by individual subjects in psychophysical tasks. An ideal observer correctly detects the presence and absence of stimuli with equal probability (curve b). An observer who is told to respond to the slightest indication of a stimulus reports many false positives when no stimuli occur and has low sensory thresholds (curve a). An observer who is told to respond only when very certain that a stimulus has occurred reports more hits than false positives and has high sensory thresholds (curve c).

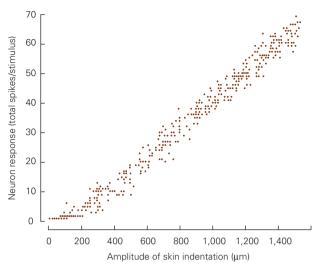

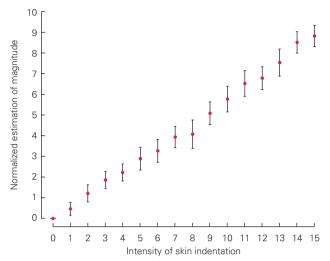

Figure 21–3 The firing rates of sensory nerves encode the stimulus magnitude. The data in the two plots suggest that the neural coding of stimulus intensity is faithfully transmitted from peripheral receptors to cortical centers that mediate conscious sensation. (Adapted, with permission, from Mountcastle, Talbot, and Kornhuber 1966.)

A. The number of action potentials per second recorded from a touch receptor in the hand is proportional to the amplitude of skin indentation. Each dot represents the response of the receptor to pressure applied by a small probe. The relationship

B Perceived sensation intensity

between the neural firing rate and the pressure stimulus is linear. This receptor does not respond to stimuli weaker than 200 µm, its touch threshold.

B. Estimates made by human subjects of the magnitude of sensation produced by pressure on the hand increase linearly as a function of skin indentation. The relation between a subject's estimate of the intensity of the stimulus and its physical strength resembles the relation between the discharge frequency of the sensory neuron and the stimulus amplitude.

described earlier; and (3) the method of adjustment or reproduction, in which a subject adjusts a second stimulus to match or reproduce the intensity of the first one.

The next major methodological and conceptual developments in psychophysics came almost a century later when S. S. Stevens introduced the technique of magnitude estimation, whereby subjects use a numerical scale to rate the intensity of the sensations experienced by stimuli of different amplitude (Figure 21–3). Verbal reports of subjective experience are widely used because they are usually reliable and repeatable. *Reliability* is assessed by correlations between observers rating the same stimuli; *repeatability* is measured by correlations between responses from the same subject to similar stimuli.

Stevens generalized the method of direct verbal reporting by defining four scales of measurement—the nominal, ordinal, interval, and ratio scales—and specifying appropriate methods for analyzing data of each type. On *nominal scales* items have names but not rank; examples are names of colors, tastes, and smells. On *ordinal scales* items are ranked with a

logical range and ordered relationship to each other, but the intervals between them cannot be compared meaningfully. Verbal descriptors of pain intensity are an example of an ordinal scale. When a clinician says, "On a scale from 1 to 10 in which 10 is the worst imaginable pain, how would you rate your pain?" there is no suggestion that the pain associated with an 8 is twice as intense as the pain associated with a 4 or that the difference between 5 and 6 equals the difference between 1 and 2.

On *interval scales* distances but not ratios between values have meaning. Counts of the number of stimuli delivered in a session or estimates of the position of an object on a grid map are examples of interval scales. In *ratio scales* the concepts of rank, interval, and ratio all have valid meanings. Estimates of the perceived intensity of a stimulus are treated as ratio scales. Subjects are instructed to assign a number proportional to the perceived intensity when a stimulus is detected, and to report "zero" when they feel no stimulus. Subjects typically choose their own numerical scale within a session. The values measured during an experiment are then normalized to allow comparisons of stimulus ratings

between subjects. These scales permeate modern statistics and are used widely beyond the field of experimental psychology for which they were developed.

Sensations Are Quantified Using Probabilistic Statistics

Decision theory offers another approach to measurement of sensations by using statistical methods to explain the variability of subjects' responses or false reports. When subjects are pressed to detect the weakest possible stimuli, they give many false-positive responses; that is they respond affirmatively in catch trials in which no stimulus was presented. As a result, the psychophysical thresholds measured are very low (Figure 21–2B, blue curve). Conversely, when subjects are told to avoid false positives, their perceptual thresholds become quite elevated. Trials in which strict criteria are used yield higher than normal threshold values (Figure 21–2B, red curve).

In 1927 L. L. Thurstone proposed that the variability of sensations evoked by a stimulus could be represented as a normal or Gaussian probability function with a mean (m_s) and a standard deviation (σ_s):

$$F(x) = (2\pi\sigma_s^2)^{-1/2} \exp[-(x - m_s)^2/2\sigma_s^2].$$

This allowed him to use the mathematics of probability theory and statistical tables to predict the discriminability of pairs of stimuli that differed along a physical dimension such as intensity. He proposed to equate the physical distance between the amplitudes of two stimuli to a psychological scale value of inferred loudness called the *discrimination index* or d'. He equated the number of correct responses (hits) and error trials (false positives when one stimulus is confused with another) with the sensory overlap of the two stimuli. This allowed him to use statistical tables of the normal probability function to calculate d' values (Box 21–1).

Decision theory methods were first applied to psychophysical studies in 1954 by the psychologists Wilson Tanner and John Swets. They developed a series of experimental protocols for stimulus detection that allowed accurate calculation of d' as well as techniques for measurement of subjective bias during sensory testing. Their methods were initially developed for engineers studying the detection of very weak radar pulses reflected from distant airplanes. As the engineers lowered the threshold for detection they detected more radar pulses, but their apparatus gave more false positives because it was triggered more frequently by noise. Tanner and Swets hypothesized that subjects gave false-positive responses when the sensory noise exceeded their response threshold.

Signal detection theory has been widely applied in sensory discrimination tests that require the subject to make a binary choice. Threshold measurements are a good example. In a "yes-no" experiment the beginning and end of an observation interval are cued, and the subject is required to say whether or not a signal, such as a tone, was present. We can represent trial-totrial fluctuations of the perceived stimulus intensity and that of the silent "noise" period as two overlapping Gaussian curves. The subject says "yes" when the signal exceeds a criterion (called a decision boundary) that has been set by the subject, and "no" when it does not. When the stimulus is very weak the neural signal it evokes is very small, and there is considerable overlap between the pure noise and the stimulus signal plus noise. Hence there is no decision boundary that allows error-free responses. Nevertheless, the mathematical formulation of the probability density function allows the experimenter to compensate for subjective differences in response criteria in calculations of d'(Box 21-1).

Sensory thresholds can also be measured using a two-alternative forced-choice protocol in which there are two observation intervals. The subject is asked whether the stimulus occurred in the first or second interval. The two-interval procedure is widely used for measuring relative intensity or sensory quality because the results obtained are more accurate than verbal judgments and the responses required are simple. Subjects can also provide nonverbal responses in such tests using levers, buttons, or other manipulanda that allow accurate measurement of decision times. Such instrumented behaviors allow neuroscientists to measure sensory processes in experimental animals by training them to use these tools to make easy sensory judgments. Such techniques can be used to probe the sensory capabilities of animal subjects as the discrimination tasks become more difficult and to investigate the underlying neural mechanisms when electrophysiological and behavioral studies are combined in the same experiment.

Decision Times Are Correlated with Cognitive Processes

Another important quantitative measure of psychophysical behavior is the *reaction time*, which is the time taken to perform a perceptual task. Franciscus Donders was the first, in 1865, to measure the time required to respond to stimuli. He and others found that reaction times elicited by strong stimuli are shorter than those elicited by weak stimuli. Similarly, in forced-choice tasks the time required for a decision is shorter when

the stimuli are clearly distinctive in intensity or quality than when they are near the discrimination threshold. Reaction times are widely used as measures of certainty of responses in humans and animals. They are often correlated with neural activity in sensory areas of the brain and in studies of sensory-triggered motor behaviors.

Reaction times are also used to evaluate cognitive function. The tasks illustrated in Figure 21–5 were devised by Anne Treisman to investigate the mechanisms of visual pattern recognition. The subjects were asked to locate a blue cross within an array of symbols. With some patterns the blue cross seems to "pop out," but with others the array must be carefully examined to find the blue cross.

One explanation for this is that when the soughtafter item differs from the other elements of the array in only one property we can scan quickly the entire array (a parallel search), but when it shares two or more properties we need to examine all of the elements oneby-one (a serial search). If this hypothesis is true, the reaction time should not depend on the *number* of elements in an array when the sought-after item differs in only one property, but it should increase in proportion to the number of elements if we must examine them individually. That is exactly the result obtained in such experiments. The same hypothesis also predicts that it should take twice as long to determine that an item is *absent* because we need to examine all elements in an array before concluding that a particular one is absent.

Subjects typically locate a sought-after item half-way through the search. The slope of the curve relating the search time to the number of elements in the array shows how long it takes to examine each element. Such experiments indicate that 30 to 50 ms is required to compare each element with the target item (Figure 21–5C). Knowing what kinds of visual features allow a parallel search and the reaction time for detecting features in a serial search provides important clues to the underlying neural mechanisms.

Physical Stimuli Are Represented in the Nervous System by Means of the Sensory Code

The psychophysical methods described in the previous section provide objective techniques for analyzing sensations evoked by particular stimuli. These quantitative measures have been combined with neurophysiological techniques to study the neural mechanisms that transform sensory signals into specific percepts.

This approach to the neural coding problem was pioneered by Vernon Mountcastle in the 1960s. He

showed that neurophysiological recordings from individual sensory neurons in the peripheral and central nervous system provide a statistical description of the neural activity evoked by a physical stimulus. He then tested hypotheses to determine which quantitative aspects of the neural response might correspond to psychophysical measurements in sensory tasks, and just as important, which do not.

The study of neural coding of information is fundamental to understanding how the brain works. A neural code describes the relationship between the activity in a specified neural population and its functional consequences for the operations that follow. The sensory systems provide a useful avenue to the study of neural coding in the brain because both the input and output of these systems can be precisely defined and quantified. Experimenters can control the physical stimuli provided to sensory receptors and measure the resulting sensations evoked by them using a variety of psychophysical techniques. By recording neuronal activity at various stages of sensory processing, neuroscientists attempt to decipher the codes that convey information in peripheral nerves and in the brain, and analyze the transformation of signals along pathways in the cerebral cortex. Indeed, study of the details of neural coding may lead to insight into the coding principles that underlie cognition.

When analyzing sensory experience it is important to realize that our conscious sensations differ qualitatively from the physical properties of stimuli because, as Kant and the idealists predicted, the nervous system extracts only certain pieces of information from each stimulus while ignoring others. It then interprets this information within the constraints of the brain's intrinsic structure and previous experience. Thus we receive electromagnetic waves of different frequencies, but we see them as colors. We receive pressure waves from objects vibrating at different frequencies, but we hear sounds, words, and music. We encounter chemical compounds floating in the air or water, but we experience them as smells and tastes. Colors, tones, smells, and tastes are mental creations constructed by the brain out of sensory experience. They do not exist as such outside the brain.

The dominant research strategy in sensory neuroscience is to follow the flow of sensory information from receptors toward the cognitive centers of the brain, attempting to understand the processing mechanisms that occur at each synaptic relay and how they shape our internal representation of the external world. The neural coding of sensory information is better understood at the early stages of processing than at later stages.

Box 21–1 Signal Detection Theory

Signal detection theory is useful for quantitative analyses of sensations in both human and animal subjects. Such studies are designed to measure comparative judgments of a physical property of a stimulus such as its intensity, size, temporal frequency, or detection threshold. They usually employ a *two-alternative forced-choice* protocol with two observation intervals and a pair of stimuli.

Subjects are asked to report whether the second stimulus is stronger or weaker, higher or lower, larger or smaller, same or different than the first stimulus. In measurements of sensory thresholds the subject is asked whether the stimulus occurred during the first or second interval. Responses in each trial are tabulated in a four-cell stimulus-response matrix in which one of the choices is designated a hit (Figure 21–4A).

For example, when measuring sensory thresholds the statistical hypothesis tested is that the stimulus occurs in the first interval. Trials in which the stimulus occurs in the first interval are labeled *hits* if the subject responds "interval 1" and *misses* if the subject responds "interval 2." Trials in which the stimulus occurs in the second interval are labeled *correct rejections* if the subject responds "interval 2," and *false positives* if the subject responds "interval 1."

The subject is considered to be an ideal observer—without any bias—if the hit rate equals the rate of correct rejection (ie, the data in the matrix are symmetric along the diagonals). In most cases subjects display an innate preference or bias for one choice or another, such that the hit rate and correct rejection rate differ (Figure 21–4B).

One can get a rough approximation of the true discrimination performance by averaging these two values. However, the most accurate estimate is obtained by using the normal distribution tables to measure the distance between the means of the stimulus and noise distributions (d'). We use the intersection of the hit rate and false-positive rate to define the amount of

overlap of the curves and to set the decision boundary (Figure 21–4B); summation of the matching z-scores provides the value of d'.

In the example shown in Figure 21–4B the subject had a very strict detection criterion and a low hit rate (65%). However, he rarely guessed that the stimulus occurred on blank trials and had a low false-positive rate (20%). As a result, the real performance is better than 65% correct. The matching percent correct calculated using signal detection methods (PC_{max}) is 73%.

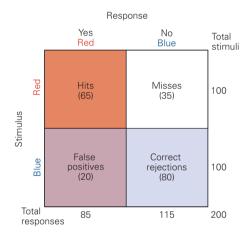

Figure 21–4A The stimulus-response matrix for a stimulus detection task (yes-no) or a categorical judgment task (red-blue). Although there are two possible stimuli and two possible responses, the data represent conditional probabilities in which the experimenter controls the stimuli and measures the subject's responses. The numbers provide examples of behavioral data obtained from a strict observer who responds "yes" less often than the actual frequency of occurrence of the stimulus. (Adapted, with permission, from Green and Swets 1966.)

Sensory Receptors Are Responsive to a Single Type of Stimulus Energy

It is often said that the power of the brain lies in the millions of neurons processing information in parallel. That formulation, however, does not capture the essential difference between the brain and all the other organs of the body. The power of a kidney or a muscle lies in the parallel action of many cells, each doing the

same thing; if we understand a muscle cell, we essentially understand how a whole muscle works. The power of the brain lies in the parallel action of millions of cells, each doing something *different*; to understand the brain we need to understand how its tasks are organized and how individual neurons carry out those tasks.

Functional differences between sensory systems arise from the different stimulus energies that drive

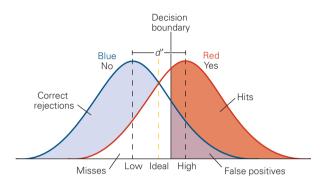

Figure 21–4B The stimuli tested in a discrimination task are represented by Gaussian curves with standard deviations that measure the fluctuation in sensations from trial to trial. The discriminability of a pair of stimuli is correlated with the distance between the peaks of the two curves (d') and the amount of overlap between them. When two stimuli are similar in magnitude, the two Gaussian curves overlap and no single criterion allows error-free responses. The frequency of hits and false positives (and their complements, misses and correct rejections) is determined by the criteria used in the decision task. An ideal observer maximizes the number of correct responses and minimizes the total errors, setting the decision boundary at the intersection of the two curves (orange dashed line). A strict observer minimizes the number of false positives but also reduces the total hits, setting the decision boundary to the right (solid line). A lax observer maximizes the number of hits but also increases the total false positives, setting the decision boundary to the left of the ideal subject. Judgments are not always ideal because the observer must balance the benefits of correct choices (hits and correct rejections) and the consequences of errors (misses and false-positive responses). (Adapted, with permission, from Green and Swets 1966.)

Subjects' response criteria can be manipulated experimentally by altering the rewards and penalties for correct and incorrect responses. Signal detection theory predicts a progressive shift in the hit rate and false-positive responses as the payoffs increase. Similarly, alteration in the frequency of presentation of one or the other stimulus in a particular interval can also alter response probabilities.

Signal detection techniques are also used in studies of categorical judgments in which a series of stimuli are classified into groups with defined names. Categorical judgments are made of spatial attributes (left/right, horizontal/vertical), colors (blue/green, black/white), shapes (round/rectangle, A/B), or physical characteristics (male/female, plant/animal, house/object). Categorical judgments are often more difficult than comparative judgments, as the subject must identify and name each sample before making a decision.

Signal detection methods have been applied recently in studies of neural responses to visual stimuli that differ in orientation, spatial frequency, or coherence of motion in order to correlate changes in neural firing rates with sensory processing. Discriminability (*d'*) is measured with *receiver operating characteristic* (ROC) analyses that compare the neural firing rates evoked by pairs of stimuli that differ in some property. The assumption is that one of the two stimuli evokes higher firing rates than the other; *d'* is correlated with the difference in mean evoked rates and the overlap between the two distributions of activity.

ROC graphs of neural data plot the proportion of trials judged correctly (hits) and incorrectly (false positives) when the decision criteria are set at various firing levels. The area under the ROC curve provides an accurate estimate of d' for each stimulus pair. The neurometric function, plotting neural discriminability as a function of stimulus differences, corresponds closely to the psychometric function obtained in forced-choice paradigms testing the same stimuli, thereby providing a physiological basis for the observed behavioral responses.

them and the discrete pathways that comprise each system. Because of these characteristics each neuron performs a specific task, and the train of action potentials it produces has a specific functional significance for all postsynaptic neurons. This basic idea was expressed in the theory of specificity set forward by Charles Bell and Johannes Müller in the 19th century and remains one of the cornerstones of sensory neuroscience.

The richness of sensory experience begins with millions of highly specific sensory receptors. Each receptor responds to a specific kind of energy at specific locations on the body and sometimes only to energy with a particular temporal or spatial pattern. The receptor transforms the stimulus energy into electrical energy, thus establishing a common signaling mechanism in all sensory systems. The amplitude and duration of the electrical signal produced by the receptor, termed the

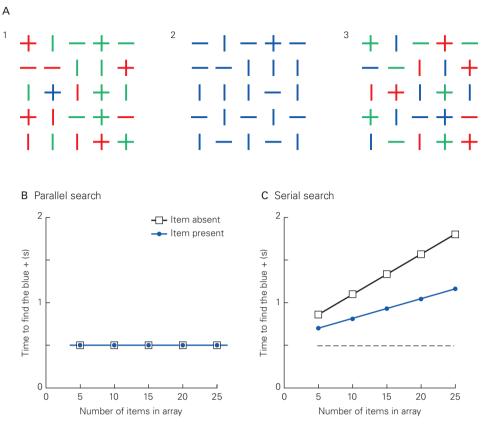

Figure 21–5 Reaction times are used to investigate the mechanisms of pattern recognition. (Modified, with permission, from Treisman 1991.)

A. Visual stimuli used to investigate the mechanisms of pattern recognition in humans. Subjects are asked to find the blue cross in each array. The task is easy with the array at left because the blue cross is the only blue item and therefore seems to "pop out." Detection is harder with the middle array because all of the items are the same color, but only one has two line segments. In the array at right, detection is difficult because the blue cross has the same shape as eight of the items and the same color as another eight. Each of the items must be examined individually to find the right one.

B. The time needed (reaction time) to detect the blue cross in arrays 1 and 2 is independent of the total number of objects because the items are similar in color or shape, allowing all of the objects to be scanned together (parallel search).

C. The time needed to detect the blue cross in an array of items that vary in shape or color (as in array 3) increases in proportion to the number of items when they share at least one property (color or shape in this example) because the search must examine each item (serial search). On average, the target item is found halfway through the search. It takes twice as long to determine that an item is *absent* because all of the objects must be examined.

receptor potential, are related to the intensity and time course of stimulation of the receptor. The process by which specific stimulus energy is converted into an electrical signal is called *stimulus transduction*.

Sensory receptors are morphologically specialized to transduce specific forms of energy, and each receptor has a specialized anatomical region where stimulus transduction occurs. Most receptors are optimally selective for a single type of stimulus energy, a property termed *receptor specificity*. We see particular colors, for example, because we have receptors that are selectively sensitive to photons with specific wavelengths,

and we smell particular odors because we have receptors that bind specific odorant molecules (Figure 21–6).

Human sensory receptors are classified as mechanoreceptors, chemoreceptors, photoreceptors, or thermoreceptors (Table 21–1). Mechanoreceptors and chemoreceptors are the most widespread and the most varied in form and function.

Six different kinds of mechanoreceptors that sense skin deformation, motion, stretch, and vibration are responsible for the sense of touch. Muscles contain three kinds of mechanoreceptors that signal muscle length, velocity, and force, whereas other mechanoreceptors in the joint capsule signal joint angle. Hearing is based on two kinds of mechanoreceptors, inner and outer hair cells, that transduce motion of the basilar membrane in the inner ear. Other hair cells in the vestibular labyrinth sense motion and acceleration of the fluids of the inner ear to signal head motion and orientation. Visceral mechanoreceptors detect the distension of internal organs such as the bowel and bladder. Osmoreceptors in the brain, which sense the state of hydration, are activated when a cell swells. Certain mechanoreceptors report extreme distortion that threatens to damage tissue; their signals reach pain centers in the brain.

Chemoreceptors are responsible for olfaction, gustation, itch, pain, and many visceral sensations. A significant part of pain is due to chemoreceptors that detect molecules spilled into the extracellular fluid by tissue injury and molecules that are part of

the inflammatory response. Several kinds of thermoreceptors in the skin sense skin warming and cooling. Another thermoreceptor, which monitors blood temperature in the hypothalamus, is mainly responsible for whether we feel warm or cold.

Vision is mediated by four kinds of photoreceptors in the retina. The light sensitivities of these receptors define the visible spectrum. The photopigments in rods and cones detect electromagnetic energy of wavelengths that span the range 390 to 670 nm (Figure 21–7A). Unlike some other species, such as birds or reptiles, humans do not detect ultraviolet light or infrared radiation because we lack receptors that detect the appropriate short or long wavelengths. Similarly, radio waves and microwave energy bands are not perceived because humans have not evolved receptors for these frequencies.

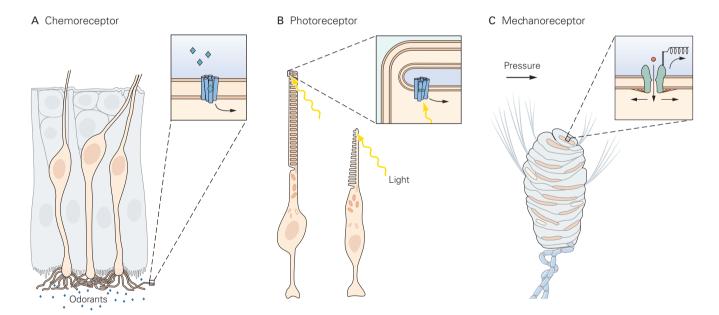

Figure 21–6 Sensory receptors are specialized to transduce a particular type of stimulus energy into electrical signals. Sensory receptors are classified as chemoreceptors, photoreceptors, or mechanoreceptors depending on the class of stimulus energy that excites them. They transform that energy into an electrical signal that is transmitted along pathways that serve one sensory modality. The insets in each panel illustrate the location of the ion channels that are activated by stimuli.

A. The olfactory hair cell responds to chemical molecules in the air. The olfactory cilia on the mucosal surface bind specific odorant molecules and depolarize the sensory nerve through a second-messenger system. The firing rate signals the concentration of odorant in the inspired air.

B. Rod and cone cells in the retina respond to light. The outer segment of both receptors contains the photopigment

rhodopsin, which changes configuration when it absorbs light of particular wavelengths. Stimulation of the chromophore by light reduces the concentration of cyclic guanosine 3', 5'-monophosphate (cGMP) in the cytoplasm, closing cation channels and thereby hyperpolarizing the photoreceptor. (Adapted, with permission, from Shepherd 1994.)

C. Meissner's corpuscles respond to mechanical pressure. The fluid-filled capsule (blue) surrounding the sensory nerve endings (pink) is linked to the fingerprint ridges by collagen fibers. Pressure or motion on the skin opens stretch-sensitive ion channels in the nerve fiber endings, thus depolarizing them. (Adapted, with permission, from Andres and von Düring 1973.)

Table 21-1 Classification of Sensory Receptors

Sensory system	Modality	Stimulus	Receptor class	Receptor cells
Visual	Vision	Light (photons)	Photoreceptor	Rods and cones
Auditory	Hearing	Sound (pressure waves)	Mechanoreceptor	Hair cells in cochlea
Vestibular	Head motion	Gravity, acceleration, and head motion	Mechanoreceptor	Hair cells in vestibular labyrinths
Somatosensory				Cranial and dorsal root gan- glion cells with receptors in:
	Touch	Skin deformation and motion	Mechanoreceptor	Skin
	Proprioception	Muscle length, muscle force, and joint angle	Mechanoreceptor	Muscle spindles and joint capsules
	Pain	Noxious stimuli (thermal, mechanical, and chemical stimuli)	Thermoreceptor, mechanoreceptor, and chemoreceptor	All tissues except central nervous system
	Itch	Histamine	Chemoreceptor	Skin
	Visceral (not painful)	Wide range (thermal, mechanical, and chemical stimuli)	Thermoreceptor, mechanoreceptor, and chemoreceptor	Gastrointestinal tract, urinary bladder, and lungs
Gustatory	Taste	Chemicals	Chemoreceptor	Taste buds
Olfactory	Smell	Odorants	Chemoreceptor	Olfactory sensory neurons

Multiple Subclasses of Sensory Receptors Are Found in Each Sense Organ

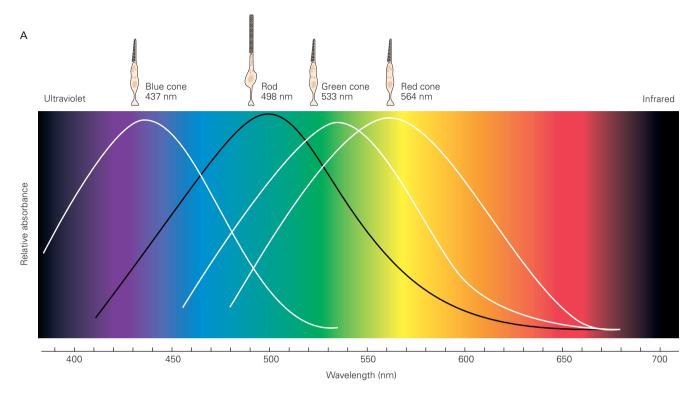

Sensory receptors are found in specialized epithelia called sense organs, principally the eye, ear, nose, tongue, and skin. The arrangement of receptors in an organized structure allows further specialization of function within each sensory system.

Each major sensory system has several constituent qualities or *submodalities*. For example, taste can be sweet, sour, salty, or bitter; objects that we see differ in color; and touch has qualities of temperature, texture, and rigidity. Submodalities exist because each class of receptors contains a variety of specialized receptors that respond to limited ranges of stimulus energies.

The receptor behaves as a filter for a narrow range or bandwidth of energy. For example, an individual photoreceptor is not sensitive to all wavelengths of light but only to a small part of the spectrum. We say that a receptor is *tuned* to an optimal or best stimulus, the unique stimulus that activates the receptor at low energy and evokes the strongest response. As a result, we can plot a tuning curve for each receptor

based on physiological experiments (the white and black curves in Figure 21–7A). The tuning curve shows the range of sensitivity of the receptor, including its threshold, the minimum stimulus intensity at which the receptor is activated. For example, blue cones in the retina are most sensitive to light of 437 nm; for that reason, they are also termed S or short-wavelength receptors. Green cones, termed M receptors for their sensitivity to middle wavelengths, respond best to 533 nm; red cones, the L or long-wavelength receptors, respond most vigorously to 564 nm wavelengths. The blue, green, and red cones respond to other wavelengths of light but these responses are weaker (see Chapter 26).

The graded sensitivity of photoreceptors means that each rod and cone responds to a wide spectrum of colors yet signals a specific wavelength by the amplitude of the evoked receptor potential. However, because the tuning curve is symmetric around the best frequency, wavelengths of greater or lesser values may evoke identical responses. For example, red cones respond equally well to light of 520 and 600 nm. How does the brain interpret these signals?

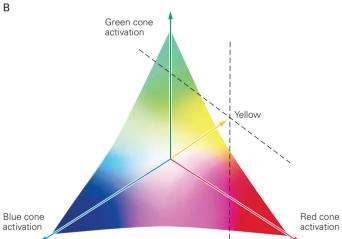

Figure 21–7 Human perception of colors results from the simultaneous activation of three different classes of photoreceptors in the retina.

A. The visible spectrum of light spans wavelengths of 390 to 670 nm. Individual rod or cone photoreceptors are sensitive to a broad range of wavelengths (black and white curves), but each is most responsive to light in a particular spectral band. As a result, cone photoreceptors are classified as red, green, and blue types. The specific colors perceived result from the relative activation of the three cone types. (Adapted, with permission, from Dowling 1987.)

B. The neural coding of color and brightness in the retina can be portrayed as a three-dimensional vector in which the strength of activation of each cone type is plotted along one of the three axes. Each point in this three-dimensional space represents a unique pattern of activation of the three cone types. The direction of the vector represents the relative activation of the three cone types and the color seen. In the example shown here strong activation of red cones, moderate stimulation of green cones, and weak activation of blue cones produces the perception of yellow. The length of the vector from the origin to the point represents the intensity or brightness of light in that region of the retina.

The answer lies with the green and blue cones. Green cones respond very strongly to light of 520 nm, as it is close to their preferred wavelength, but respond weakly to 600 nm light. Blue cones do not respond to 600 nm light and are barely activated at 520 nm. As a result, 520 nm light is perceived as green, whereas 600 nm is seen as orange. Thus we are able to perceive a spectrum of colors through varying combinations of photoreceptors.

Similarly, the complex flavors we perceive when eating are a result of combinations of chemoreceptors of varying affinities for natural ligands. The broad tuning curves of a large number of distinct olfactory and gustatory receptors afford endless combinatorial possibilities.

Neural Firing Patterns Transmit Sensory Information to the Brain

The receptor potential generated by an adequate stimulus produces a local depolarization or hyperpolarization of the sensory receptor cell. However, the sense organs are located at distances far enough from the central nervous system that passive propagation cannot suffice to convey signals there. To communicate sensory information to the brain a second step in neural coding must occur. The change in membrane potential produced by the sensory stimulus is transformed into action potentials that can be propagated over long distances.

Action potentials are generated in olfactory sensory neurons and dorsal root ganglion neurons of the somatosensory system whose axons project directly to the central nervous system. In the auditory, vestibular, and gustatory (taste) systems the receptor cells make synaptic contact with the peripheral branches of the sensory axons that form cranial nerves VIII, VII, and IX. The retina has the most elaborate neural network for processing sensory information. Photoreceptors send signals through a series of local interneurons to retinal ganglion cells that transform visual information into bursts of action potentials that travel to the brain through the optic nerve.

Sensory receptors encode the intensity of the stimulus in the amplitude of the receptor potential. This analog signal of intensity is transformed into a digital pulse code in which the frequency of action potentials is proportional to the intensity of the stimulus (see Figure 21–3A). The notion of an analog-to-digital transformation dates back to 1925 when Edgar Adrian and Yngve Zotterman discovered the all-or-none properties of the action potential in sensory neurons. Zotterman would later write:

November 2, 1925, was a red letter day for both of us.... We were excited, both of us quite aware that what we now saw had never been observed before and that we were discovering a great secret of life, how the sensory nerves transmit their information to the brain.... We had found that the transmission in the nerve fiber occurred according to impulse frequency modulation (FM) twenty years before FM was introduced in teletechnique.

Despite the rather crude recording instruments available at that time, Adrian and Zotterman discovered that the frequency of firing—the number of action potentials per second—varies with the strength of the stimulus and the time over which it has been in action; stronger stimuli evoked larger receptor potentials that generated a greater number and a higher frequency of action potentials.

In later years, as recording technology improved and digital computers allowed precise quantification of the timing of action potentials, Mountcastle and his colleagues demonstrated a precise correlation between sensory thresholds and neural responses, as well as the parametric relationship between neural firing rates and self-reports of the intensity of sensations (see Figure 21–3). They also found that the dynamics of the spike train conveys important information about fluctuations of the stimulus, such as the frequency of vibration or a change in rate of movement. Humans can report changes in sensory experience that correspond to alterations in the firing patterns of sensory neurons in the range of a few milliseconds.

The temporal properties of a changing stimulus are encoded as changes in the pattern of sensory neuron activity. Many sensory neurons signal the rate at which stimulus intensity changes by rapidly altering their firing rates. For example, in slowly adapting mechanoreceptors the initial spike discharge when a probe touches the skin is proportional to both the speed at which the skin is indented and the total amount of pressure (Figure 21–8A). During steady pressure the firing rate slows to a level proportional to skin indentation. Firing stops when the probe is retracted. Thus, neurons signal important properties of stimuli not only when they fire but also when they stop firing.

The instantaneous firing patterns of sensory neurons are as important to sensory perception as the total number of spikes fired over long periods. Steady rhythmic firing in nerves innervating the skin is perceived as vibration or steady pressure. Bursting patterns may be perceived as motion. If a stimulus persists unchanged for several minutes without a change in position or amplitude, the neural response diminishes and sensation is lost, a condition called *receptor adaptation*.

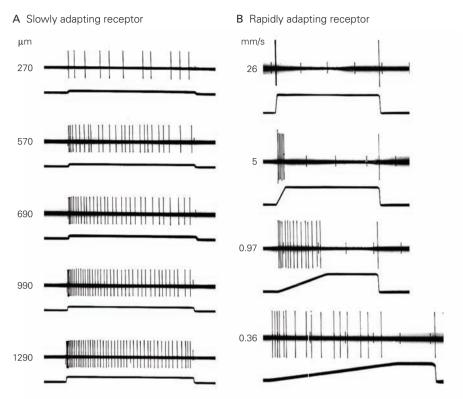

Figure 21–8 Firing rates of sensory neurons convey information about the stimulus intensity and time course. These records illustrate responses of two different classes of touch receptors to a probe pressed into the skin. The stimulus amplitude and time course are shown in the lower trace of each pair; the upper trace shows the action potentials recorded from the sensory nerve fiber in response to the stimulus.

A. A slowly adapting mechanoreceptor responds as long as pressure is applied to the skin. The total number of action potentials discharged during the stimulus is proportional to the amount of pressure applied to the skin. The firing rate is higher at the beginning of skin contact than during steady pressure,

as this receptor also detects how rapidly pressure is applied to the skin. When the probe is removed from the skin, the spike activity ceases. (Adapted, with permission, from Mountcastle, Talbot, and Kornhuber 1966.)

B. A rapidly adapting mechanoreceptor responds at the beginning and end of the stimulus, signaling the rate at which the probe is applied and removed; it is silent when pressure is maintained at a fixed amplitude. Rapid motion evokes a brief burst of high-frequency spikes, whereas slow motion evokes a longer-lasting, low-frequency spike train. (Adapted, with permission, from Talbot et al. 1968.)

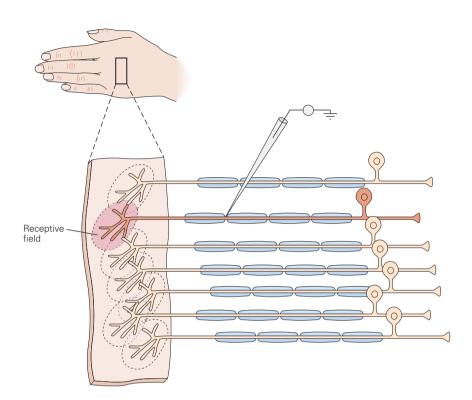

Receptor adaptation is thought to be an important neural basis of perceptual adaptation, whereby a constant stimulus fades from consciousness. Receptors that respond to prolonged and constant stimulation, known as slowly adapting receptors, encode stimulus duration by generating action potentials throughout the period of stimulation. In contrast, rapidly adapting receptors respond only at the beginning or end of a stimulus; they *cease* firing in response to constant amplitude stimulation and are active only when the stimulus intensity increases or decreases (Figure 21–8B).

The existence of two kinds of receptors—rapidly and slowly adapting sensors—illustrates another important principle of sensory coding. Sensory systems

detect *contrasts* in discrete stimuli, changes in the temporal and spatial patterns of stimulation.

The intensity of a stimulus is also represented in the brain by the total number of active neurons in the receptor population. This type of *population code* depends on the fact that individual receptors in a sensory system differ in their sensory thresholds or in their affinity for particular molecules. Most sensory systems have low- and high-threshold receptors. When stimulus intensity changes from weak to strong, low-threshold receptors are first recruited, followed by high-threshold receptors. Parallel processing in low- and high-threshold pathways extends the dynamic range of a sensory system by overcoming the maximum firing rate of 1,000 spikes per second imposed by

Figure 21-9 The receptive field of a sensory neuron is the spatial domain in the sense organ where stimulation excites or inhibits the neuron. The receptive field of a touch-sensitive neuron denotes the region of skin where gentle tactile stimuli evoke action potentials in that neuron. It encompasses all of the receptive endings and terminal branches of the sensory nerve fiber. If the fiber is stimulated electrically with a microelectrode, the subject experiences touch localized to the receptive field on the skin. The area from which the sensation arises is called the perceptive field. A patch of skin contains many overlapping receptive fields, allowing sensations to shift smoothly from one sensory neuron to the next in a continuous sweep. The axon terminals of sensory neurons in the central nervous system are arranged somatotopically, providing an orderly map of the innervated region of the body.

the absolute refractory period. For example, rod cells in the retina are activated in very dim light but reach their maximal receptor potentials in daylight. Cone cells do not respond in dim light but sense differences in brightness in daylight. The combination of the two types of photoreceptors allows us to perceive light intensity over several orders of magnitude.

As this discussion illustrates, the possibilities for information coding through temporal patterning within and between neurons in a population are enormous. For example, the timing of action potentials in the presynaptic cell can determine whether the post-synaptic cell fires. Two action potentials that arrive synchronously or nearly so will drive the postsynaptic neuron's membrane potential much further toward or away from the threshold for an action potential than would asynchronous action potentials. The timing of action potentials between neurons also has a profound effect on long-term potentiation and long-term depression at synapses (see Chapter 67).

The Receptive Field of a Sensory Neuron Conveys Spatial Information

Populations of neurons are also important for conveying the spatial properties of stimuli in a variety of modalities. The spatial attributes of visual, tactile,

and auditory stimuli include the location, dimensions, shape, and tonal frequency of the stimuli. The spatial attributes of proprioceptive stimuli include the length of muscles, joint postures, and the body's orientation in the gravitational field. These properties are linked to the anatomical arrangement of receptors within each sense organ.

The position of a sensory neuron in the sense organ is a major element of the specific information conveyed by that neuron (Figure 21–9). The skin area or region of space or tonal domain in which stimuli can activate a sensory neuron is called its *receptive field*. The skin area or region of space from which a sensation seems to arise is called the neuron's *perceptive field*. The two usually coincide.

The dimensions of receptive fields play an important role in the ability of a sensory system to encode spatial information. The objects that we see with our eyes or hold in our hands are much larger than the receptive field of an individual sensory neuron, and therefore stimulate groups of adjacent receptors. The size of the stimulus therefore influences the total number of receptors that are activated. In this manner the spatial distribution of active and silent receptors provides a neural image of the size and contours of the stimulus. This pattern is called an *isomorphic representation* of the stimulus.

Each receptor in the active population encodes the type of energy applied to the receptive field, the local stimulus magnitude, and its temporal properties. For example, auditory codes describe the tonal frequency, loudness, and duration of sound-pressure waves hitting the ear, whereas visual codes describe the hue, brightness, and time course of light hitting the retina. The neural representation of an object or scene is therefore composed of a mosaic of individual receptors that collectively signal its size, contours, texture, color, and temperature.

A good way to visualize the neural activity of a population of neurons, and to grasp the range of possibilities for population coding, is to think of neurons as points in a visual display that flash brightly whenever an action potential occurs. If the action potentials occur at random times, one would perceive a disorganized pattern of flickering dots like the "snow" on old-style television screens without a signal. However, if groups of pixels are turned on and off synchronously, coherent spatial patterns appear. Similarly, when a horizontal bar of light stimulates a row of adjacent photoreceptors in the retina, action potentials are generated in neighboring ganglion cells. Although each photoreceptor simply registers light in its receptive field, the pattern of a bar emerges from the population of active ganglion cells. Neurons in the central nervous system decipher the image of a bar by responding preferentially to specific ensembles of active receptors.

Synchronous patterns of activity in sensory neuron populations convey the spatial dimensions of the stimulus but do not in themselves signal its intensity. The brightness and contours of a video image are created by modulation of the luminance of each pixel. Similarly, in neural codes signal strength is conveyed by the impulse rates of the individual neurons. This is called rate coding. The temporal integration of action potentials that occurs at synapses smooths the staccato on-off firing patterns into a continuous modulated signal analogous to the gray scale of a video monitor. High firing rates in this model yield white zones, intermediate rates produce gray zones, and silence gives a black region. Rate coding thereby allows the population of neurons to simultaneously transmit the spatial properties and intensity of stimuli.

The spatial resolution of a sensory system is proportional to the total number of receptor neurons and how their receptive fields are apportioned within the population (Figure 21–10). Regions of a sense organ with a high density of receptors, such as the central retina (the fovea), have small receptive fields because the terminals of each sensory neuron are confined to a local cluster of receptors. Each retinal ganglion cell in the fovea measures the average light intensity in a small spot of the visual field; but because there are so many of them, the population of cells in the fovea transmits a very detailed representation of the visual scene.

A 20 × 20 pixels

B 60×60 pixels

C 400 × 400 pixels

Figure 21–10 The spatial properties of scenes and objects are conveyed by populations of neurons, each of which represents a small component of the image. The resolution of detail is inversely correlated with the area of the receptive field of individual neurons. Each square or pixel in these images represents a receptive field. The gray scale in each pixel is proportional to the average light intensity in the corresponding receptive field. If there are a small number of neurons, and

each spans a large area of the image, the result is a very schematic representation of the scene (A). As the density of neurons increases, and the size of each receptive field decreases, the spatial detail becomes clearer (B, C). The increased spatial resolution comes at the cost of larger populations of neurons required to transmit the information. (Photographs reproduced with permission of Daniel Gardner.)

Ganglion cells in the periphery of the retina have larger receptive fields because the receptor density is much lower. The dendrites of each ganglion cell receive information from a wider area of the retina, and thereby integrate light intensity over a greater portion of the visual field. This arrangement yields a less detailed image of the scene (Figure 21–10A). Similarly, the region of the body most often used to touch objects is the hand. Not surprisingly, mechanoreceptors for touch are concentrated in the fingertips, and the receptive fields on the hand are smaller than those on the arm or trunk.

Spatial coding is ubiquitous for two reasons. First, it takes advantage of the parallel architecture of the nervous system. The number of neurons in each unimodal area of sensory cortex is approximately 100 million. Thus the possible number of spatial patterns of neural activity greatly exceeds the number of atoms in the universe. Second, each neuron is a spatial as well as a temporal decoder: It fires only when many of its excitatory synapses receive action potentials and most of the inhibitory synapses do not. That is, it fires in response to some patterns of stimulation and not others. The fact that on average each cortical neuron has 10,000 synapses makes the number of spatial coding possibilities enormous.

Spatial codes are sometimes called vector codes from the mathematical idea of vector spaces. The firing rate of each neuron in a population can be plotted in a coordinate system with multiple axes such as modality, location, intensity, and time. The neural components along these axes combine to form a vector that represents the population's activity (see Figure 21–7B). The vector interpretation is useful because it makes available powerful mathematical techniques.

The fragmentation of a stimulus into components, each encoded by an individual neuron, is the initial step in sensory processing. Assembly of the components into an internal representation of an object occurs within neural networks in the brain. This process allows the brain to abstract certain features of an object, person, scene, or external event from the detailed receptor input. As a result, the internal representation formed in the brain may exaggerate some features that are important at the moment while ignoring others. In this sense our percepts are not perfect mirrors of the stimuli that evoke them but instead a creation of the mind.

Modality-Specific Pathways Extend to the Central Nervous System

Bell and Müller realized that the richness provided by the specificity of our receptors would be lost without connections to brain centers that are as rich and varied as the receptors themselves. A sensory neuron's action potentials have a specific effect on our sensory experience because of the neuron's central connections, not because of the stimulus that evokes the action potentials. Action potentials in nerve fibers of the cochlea, for example, evoke the sensation of a tone whether activated by sound waves or by electrical stimulation with a neural prosthesis.

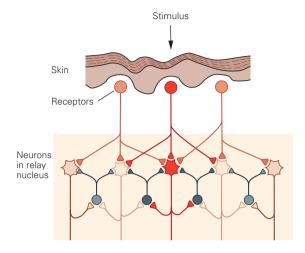

Each class of sensory receptors makes connections with structures in the central nervous system that are dedicated to one sensory modality, at least in the early stages of information processing. Thus sight or touch is experienced because specific central nervous structures are activated. Each sensory modality is therefore represented by the ensemble of central neurons connected to a specific class of receptors. Such ensembles of neurons are referred to as *sensory systems*, which include the somatosensory, visual, auditory, vestibular, olfactory, and gustatory systems (see Table 21–1).

Sensory information flows through pathways dedicated to conveying stimulus information before ending in brain regions that are more clearly concerned with cognition and action than with sensory processing. However, synaptic relays in sensory pathways do more than simply pass on signals received. Each relay neuron receives convergent excitatory synaptic inputs from many neurons in the presynaptic pathway. Likewise, each receptor neuron excites a large number of postsynaptic neurons. In addition, inhibitory interneurons in the relay nucleus modulate the excitability of relay neurons, thereby regulating the amount of sensory information transmitted centrally to higher levels of the network (Figure 21–11).

Like the primary sensory neurons in the periphery, neurons in the central sensory pathways have specific receptive and perceptive fields. The specificity of a central neuron is determined by the receptive fields of the neurons that excite and inhibit it. The neuron responds optimally to stimuli that simultaneously activate a particular set of presynaptic excitatory neurons. The neuron's receptive field is also shaped by inhibitory input. The inhibitory region of a receptive field provides an important mechanism for enhancing the contrast between stimuli and thus gives the sensory systems additional power to resolve spatial detail.

The activity of sensory neurons in the brain is more variable from trial to trial than that of sensory neurons in the periphery. Central sensory neurons also fire irregularly before and after stimulation, and during periods when no stimuli are present. The variability of the evoked central responses is a result of several factors: the subject's state of alertness, whether

A Neural circuits for sensory processing

B Spatial distribution of excitation and inhibition

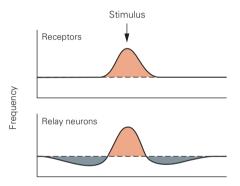

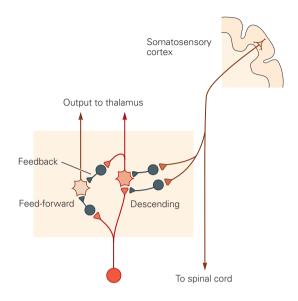

Figure 21–11 Neural networks in relay nuclei integrate sensory information from multiple receptors.

A. Sensory information is transmitted in the central nervous system through hierarchical processing networks. A stimulus to the skin is registered by a large group of postsynaptic neurons in relay nuclei in the brain stem and thalamus, but most strongly by neurons in the center of the array (red neuron). The receptive field of an individual relay neuron is larger than that of any of the presynaptic sensory neurons because of the convergent connections. (Adapted, with permission, from Dudel 1983.)

B. Inhibition (gray areas) mediated by local interneurons confines excitation (orange area) to the central zone where stimulation is strongest, enhancing the contrast between strongly and weakly stimulated relay neurons.

his or her attention is engaged, previous experience of that stimulus, and recent activation of the pathway by similar stimuli. Similarly, behavioral conditions during stimulus presentation, subjective intentions, motor plans that may evoke feedback responses, or intrinsic oscillations of the neuron's membrane potential can all C Types of inhibition in relay nuclei

C. Inhibitory interneurons in a relay nucleus are activated by three distinct excitatory pathways. Feed-forward inhibition is produced by the afferent fibers of receptors that terminate on the inhibitory interneurons. Feedback inhibition is produced by recurrent collateral axons of neurons in the output pathway from the nucleus. The interneurons in turn inhibit nearby output neurons, creating sharply defined zones of excitatory and inhibitory activity in the nucleus. In this way the most active relay neurons reduce the output of adjacent, less active neurons, permitting a winner-take-all strategy that ensures that only one of two or more competing responses is expressed. Inhibitory interneurons are also activated by neurons in other brain regions such as the cerebral cortex. The descending pathways allow cortical neurons to control the relay of sensory information centrally, providing a mechanism by which attention can select sensory inputs.

modify the incoming sensory information. For these reasons, neural responses to sensory stimulation or during motor behaviors are usually illustrated both by raster plots that depict the trial-to-trial variability of firing (see Figure 21–15) and by histograms that average neural activity across trials.

The Receptor Surface Is Represented Topographically in Central Nuclei

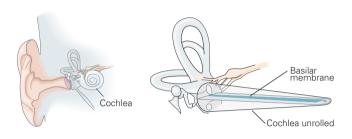

As we saw in Chapter 17, receptor axons terminate in the brain in an orderly manner forming maps of the receptor sheet. At all levels of a sensory system the stimulus sensitivity of individual neurons varies in an orderly way across a nucleus. Maps of primary specificity—the qualities to which neurons are most narrowly tuned—provide clues to the functional organization of a nucleus.

In the first relay nuclei of the somatosensory, visual, and auditory systems adjacent neurons represent adjacent areas of the body, retina, and cochlea, respectively. The organization of these nuclei is thus said to be somatotopic, retinotopic, or tonotopic. Nuclei in the auditory system are called tonotopic because the inputs from cochlear hair cells are arranged to create an orderly shift in frequency sensitivity from cell to cell, reflecting the functional organization of the hair cells in the cochlea (Figure 21–12). In other words, the firing of a particular neuron in a population signals the location of a stimulus on the receptor surface.

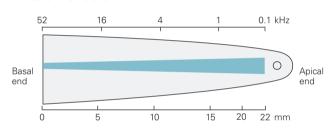

Neurons in the primary sensory areas of the cerebral cortex continue to represent location-specific features of a stimulus, and the functional maps of these areas are also somatotopic, retinotopic, or tonotopic. However, at higher levels within each sensory system neurons are more sharply selective of other stimulus features. Thus central auditory neurons are less selective for frequency and more selective for certain kinds of sound. For example, some neurons are specific for vocalizations by members of the same species. In each successive nucleus the spatial organization is progressively lost as neurons become less concerned with the descriptive features of stimuli and more concerned with properties of behavioral importance in that modality (Figure 21–13).

One of the most important insights into feature detection in the cortex arose from combined physiological and anatomical studies of the cortical visual pathways by Mortimer Mishkin and Leslie Ungerleider. They discovered that sensory information arriving in the primary visual areas is divided in two parallel pathways. One pathway conveys information needed for immediate action and the other information needed for classification of images. Visual features that identify what an object is are transmitted in a ventral pathway to the temporal lobe and eventually to the hippocampus and entorhinal cortex. Visual information about where the object is located and its size and shape is transmitted in a more dorsal pathway to the parietal lobe and eventually to the motor areas of frontal cortex (Figure 21–14).

The ventral and dorsal streams of sensory information are used as the basis of two major forms of memory: semantic memory, which allows us to talk about objects or persons, and procedural memory, which we use to interact with objects or persons.

A Basilar membrane

B Traveling wave profile

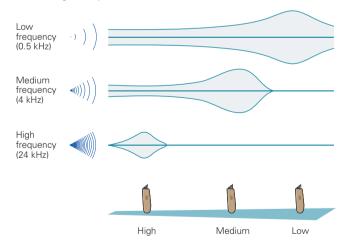

Figure 21–12 Receptors in the cochlea, the sense organ of the inner ear, are arranged tonotopically. (Adapted, with permission, from Shepherd 1994.)

A. The frequency selectivity of hair cell receptors in the cochlea is due in part to the change in dimensions along the length of the basilar membrane where the hair cells are embedded.

B. When sound is received at the cochlea, a traveling wave moves along the basilar membrane. The increasing width of the basilar membrane alters the amplitude of vibration: high frequencies evoke the greatest displacement toward the basal end, whereas low frequencies are strongest at the apical end.

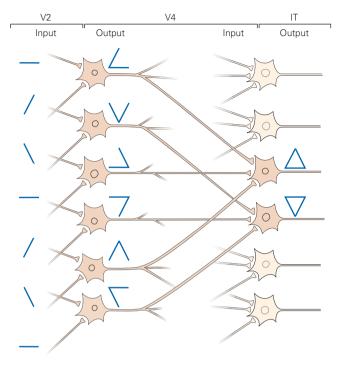

Figure 21–13 Convergent connections allow cortical neurons to abstract complex information from simple patterns. Individual neurons in primary (V1) and secondary visual cortex (V2) respond optimally to bars with specific orientations and locations in the visual field. Convergent inputs from different sets of V2 neurons enable V4 cells to signal an angle. In turn, the outputs of V4 neurons converge on neurons in the inferior temporal cortex (IT) that respond optimally to more complex shapes such as a triangle. Thus, stimulation of the retina creates fragmented representations of an object that are integrated into a recognizable form in higher cortical areas. (Adapted, with permission, from Brincat and Connor 2004.)

Ventral and dorsal streams are also evident in other sensory systems. In the auditory system acoustic information from speech is transmitted to Wernicke's area in the temporal lobe, which has a strong role in language comprehension, and to the Broca area in the frontal cortex, which is involved in speech production. In the somatosensory system information about an object's features such as size and shape is transmitted to ventral areas of parietal cortex for object recognition. Tactile information about object size, weight, and texture is also communicated to posterior parietal and frontal motor areas, where it is needed to plan handling of the object.

Feedback Regulates Sensory Coding

The sensory systems are not simply assembly lines that reassemble initial neural representations into ones that are more appropriate for cognition. That view is at odds with our own experience of sensation and perception. We have enormous control over perception and consciousness at high and low levels. At a high level, for example, we can switch our attention from the subject matter of a painting to the painter's use of form, color, and texture.

At a much lower level we can to some extent control the sensations that reach consciousness. We may, for example, watch television to take our minds off the pain of a sprained ankle. Direct, volitional control of the sensory information that reaches consciousness can be readily demonstrated by suddenly directing your attention to a body part, such as the fingers of your left hand, to which you were oblivious as you were attending to this text. Sensations from the fingers flood consciousness until attention is redirected to the text. Neural recordings in somatosensory and visual cortex indicate that neurons change their sensitivity, as reflected in their firing rates, but not their selectivity for stimuli (Figure 21–15).

Each of the sensory systems also has feedback projections. Each primary sensory cortex has extensive projections back to its principal relay nucleus in the thalamus. In fact, the number of feedback axons exceeds the number of afferent axons from the thalamus to the cortex. These projections have an important function that is not yet clear. One possibility is that they modulate the responsiveness of certain neurons when attention and vigilance change or during motor tasks.

Higher centers in the brain are also able to modulate the responsiveness of sensory receptors. For example, neurons in the motor cortex can alter the sensitivity of sensory receptors in skeletal muscle that signal muscle length. Activation of gamma motor neurons by corticospinal pathways enhances the sensory responses of muscle spindle afferents to stretch. Neurons in the brain stem can directly modulate the frequency sensitivity of hair cells in the cochlea. So even at the level of individual sensory receptors the information sent to the brain signals properties of both the stimulus and the subject who receives the information.

Top-Down Learning Mechanisms Influence Sensory Processing

What we perceive is always some combination of the sensory stimulus itself and the memories it evokes. The late coach of the Boston Celtics, Red Auerbach, once reflected that, in motivating a team, "It's not what you say to them, but what they hear that matters."

The relationship between perception and memory was originally developed by the empiricists, particularly

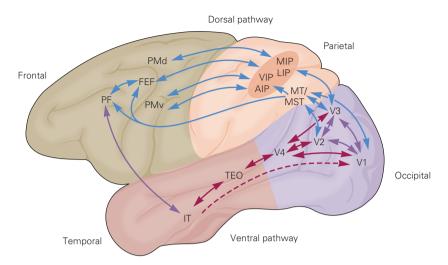

Figure 21–14 Visual stimuli are processed by serial and parallel networks in the cerebral cortex. When you read this text the spatial pattern of the letters is sent to the cerebral cortex through successive synaptic links comprising photoreceptors, bipolar cells of the retina, retinal ganglion cells, cells in the lateral geniculate nucleus of the thalamus, and layer IV neurons of the primary visual cortex (V1). Within the cortex there is a gradual divergence to successive processing areas called ventral and dorsal streams that are neither wholly serial nor parallel. The ventral stream in the temporal lobe (burgundy arrows) analyzes and encodes information about the form and structure of the visual scene and objects within it, delivering this information to the

parahippocampal cortex (not shown) and prefrontal cortex (PF). The dorsal stream in the parietal lobe (blue arrows) analyzes and represents information about stimulus location and motion and delivers this information to motor areas of the frontal cortex that control movements of the eyes, hand, and arm. The anatomical connections between these areas are reciprocal, involving both feed-forward and feedback circuits. (V1, V2, V3, and V4, occipital visual areas; MT, middle temporal; MST, medial superior temporal; AIP, VIP, LIP, and MIP, anterior, ventral, lateral, and medial intraparietal; TEO, temporal-occipital; IT, inferior temporal; PMd and PMv, dorsal and ventral premotor; FEF, frontal eye fields.) (Adapted, with permission, from Albright and Stoner 2002.)

the associationist philosophers James Mill and his son John Stuart Mill. Their idea was that sensory and perceptual experiences that occur together or in close succession, particularly those that do so repeatedly, become associated so that one thereafter triggers the other. It is easy to see how associationism verges on a theory of knowledge, thought, intelligence, and even consciousness. Association is a powerful mechanism and much of learning consists of committing associations to memory through repeated exposure.

We understand in principle how a network of neurons can "recognize" a specific pattern of inputs from a population of presynaptic neurons. The mechanism is called *template matching*. Each neuron in the target population has a pattern of excitatory and inhibitory presynaptic connections. If the pattern of arriving action potentials fits the postsynaptic neuron's pattern of synaptic connections even approximately—activates many of its excitatory synapses but mostly avoids activating its inhibitory synapses—the target neuron fires.

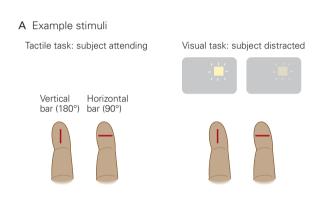

This mechanism also contains the essential elements of association. Suppose the pattern of inputs is a representation of the letter A, and the pattern of action

potentials evoked in the target population is the representation of the letter B; B then becomes associated with A. Exposure to A evokes the internal representation of B. If the representation of B is fed back to this same target population and it evokes the representation of a C, an associative chain has been established. Whether the brain uses a mechanism like this is not known, but the speed of recognition and association together with the parallel architecture of the brain suggest that something like this must occur.

This template-matching mechanism is very powerful and forms the basis of virtually all computer-based pattern-recognition schemes. Nonetheless, no artificial scheme comes close to the human ability to recognize patterns of many kinds because artificial systems cannot handle the extreme variability of sensory stimuli in the real world. In general, attempts to recognize stimuli by referring to stored records of earlier stimuli fail because of this variability; subsequent occurrences of the same or similar stimuli rarely match earlier occurrences. The general approach among computer scientists is to search for a way to separate information about the form and structure of a stimulus from

information about the properties that vary from one exposure to the next.

Whether the brain solves the recognition problem in this way is uncertain. There is currently much evidence that the neural representation of a stimulus conveyed by a large population of receptor neurons in the initial pathways of sensory systems is an isomorphic representation of the stimulus. Successive synaptic regions transform these initial neural representations into abstracted representations of our environment

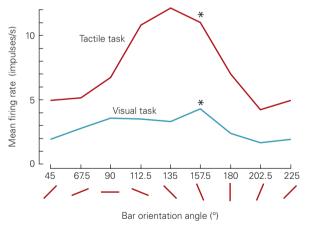

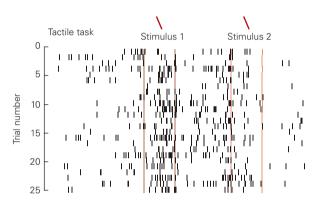

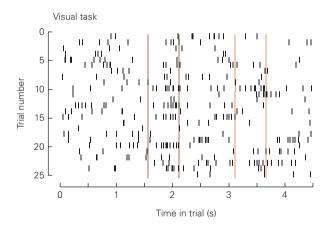

Figure 21–15 Attention to a stimulus enhances the responses of a neuron in the secondary somatosensory cortex. When we pay attention to a stimulus we are selecting certain sensory inputs for cognitive processing, and ignoring or suppressing other information. (Adapted, with permission, from Hsiao, Lane, and Fitzgerald 2002.)

A. A pair of bars was successively pressed against the skin of a monkey's fingertips while the animal performed a tactile or visual task. In the tactile task the animal was required to indicate whether the orientations of the bars were the same or different. In the visual task the animal had to detect a change in the brightness of a square displayed on a computer monitor while the bars were pressed against its fingertips.

C Neural response to both tactile stimuli

B. The mean firing rate of the neuron was significantly higher for all bar orientations when the animal attended to the tactile stimulus (tactile task) than when the stimulus was ignored (visual task). The asterisks mark the firing rates evoked by stimulus 1 (shown in part C).

C. Raster plots of the spike trains of the neuron in response to a bar oriented at the most preferred orientation of 157.5°. Each vertical tick in the plots indicates an action potential; each row represents a single trial. Vertical lines indicate the beginning and end of each stimulus. The responses to stimulus 1 were stronger in the tactile task when the animal attended to the stimulus. Stimulus 2 evoked weaker responses than stimulus 1, and was followed by a period of inhibition after the animal had made its choice.

that we are beginning to decipher. In contrast, we barely understand the top-down mechanisms by which incoming sensory information invokes memories of past occurrences and activates our subjective prejudices and opinions. These topics are difficult to analyze experimentally, particularly in animal models. When we do understand these neural codes it is likely that we will be on the verge of understanding cognition, the way in which information is coded in memory. That is what makes the study of neural coding so challenging and exciting.

An Overall View

Our sensory systems provide the means by which we perceive the external world, remain alert, form a body image, and regulate our movements. Sensations arise when external stimuli interact with some of the billion sensory receptors that innervate every organ of the body. The information detected by these receptors is conveyed to the brain as trains of action potentials traveling along individual sensory axons.

These messages are analyzed centrally by several million sensory neurons performing different, specific functions in parallel. Each sensory neuron extracts highly specific and localized information about the external or internal environment and in turn has a specific effect on sensation and cognition because it projects to specific places in the brain that have specific sensory functions.

All sensory systems respond to four elementary features of stimuli-modality, location, intensity, and duration. The diverse sensations we experience—the sensory modalities—reflect different forms of energy that are transformed by receptors into depolarizing or hyperpolarizing electrical signals called receptor potentials. Receptors specialized for particular forms of energy, and sensitive to particular ranges of the energy bandwidth, allow humans to sense many kinds of mechanical, thermal, chemical, and electromagnetic events. To maintain the specificity of each modality within the nervous system, receptor axons are segregated into discrete anatomical pathways that terminate in unimodal nuclei. After about a dozen synaptic steps in each sensory system, neural activity converges on neuronal groups whose function is polymodal and more directly cognitive.

The location and spatial dimensions of a stimulus are conveyed through each receptor's receptive field, the precise area in the sensory domain in which stimulation activates the receptor. The identity of the active sensory neurons therefore signals not only the modality of a stimulus, but also the place where it occurs. The intensity and duration of stimulation are

represented by the amplitude and time course of the receptor potential and by the total number of receptors activated. In the brain, intensity is encoded in the frequency of firing, which is proportional to the strength of the stimulus. The temporal features of a stimulus, such as duration and changes in magnitude, are signaled by the dynamics of the spike train.

The pattern of action potentials in peripheral nerves and in the brain gives rise to sensations whose qualities can be measured directly using a variety of psychophysical paradigms such as magnitude estimation and signal detection and discrimination tasks. Reaction times to stimuli also provide a means for measuring the intensity of stimulation and the ease of sensory discrimination in both human and animal subjects.

The richness of sensory experience—the complexity of sounds in a Mahler symphony, the subtle layering of color and texture in views of the Grand Canyon, or the multiple flavors of a salsa—requires the activation of large ensembles of receptors acting in parallel, each one signaling a particular aspect of a stimulus. The neural activity in a set of thousands or millions of neurons should be thought of as coordinated activity that conveys a "neural image" of specific properties of the external world.

Sensory information in the central nervous system is processed in stages, in the sequential relay nuclei of the spinal cord, brain stem, thalamus, and cerebral cortex. Each nucleus integrates sensory inputs from adjacent receptors and, using networks of inhibitory neurons, emphasizes the strongest signals. Processing of sensory information in the cerebral cortex occurs in multiple cortical areas in parallel, and is not strictly hierarchical. Feedback connections from areas of the brain involved in cognition, memory, and motor planning control the incoming stream of sensory information, allowing us to interpret sensory stimulation in the context of past experience and current goals.

The Somatosensory System: Receptors and Central Pathways

The Primary Sensory Neurons of the Somatosensory System Are Clustered in the Dorsal Root Ganglia

Peripheral Somatosensory Nerve Fibers Conduct Action Potentials at Different Rates

Many Specialized Receptors Are Employed by the Somatosensory System

Mechanoreceptors Mediate Touch and Proprioception

Proprioceptors Measure Muscle Activity and Joint Positions

Nociceptors Mediate Pain

Thermal Receptors Detect Changes in Skin Temperature

Itch Is a Distinctive Cutaneous Sensation

Visceral Sensations Represent the Status of Various Internal Organs

Somatosensory Information Enters the Central Nervous System Through Cranial and Spinal Nerves

Somatosensory Information Flows from the Spinal Cord to the Thalamus Through Parallel Pathways

The Dorsal Column–Medial Lemniscal System Relays Tactile and Proprioceptive Information

The Spinothalamic System Conveys Noxious, Thermal, and Visceral Information

The Thalamus Has a Number of Specialized Somatosensory Regions

The Ventral Posterior Nucleus Relays Tactile and Proprioceptive Information

Noxious, Thermal, and Visceral Information Is Processed in Several Thalamic Nuclei

An Overall View

Somatic information is provided by receptors distributed throughout the body. One of the earliest investigators of the bodily senses, Charles Sherrington, noted that the somatosensory system serves three major functions: proprioception, exteroception, and interoception.

Proprioception is the sense of oneself (Latin proprius, one's own). Receptors in skeletal muscle, joint capsules, and the skin enable us to have conscious awareness of the posture and movements of our own body, particularly the four limbs and the head. Although one can move parts of the body without sensory feedback from proprioceptors, the movements are often clumsy, poorly coordinated, and inadequately adapted to complex tasks, particularly if visual guidance is absent.

Exteroception is the sense of direct interaction with the external world as it impacts on the body. The principal mode of exteroception is the sense of touch, which includes sensations of contact, pressure, stroking, motion, and vibration, and is used to identify objects. Some touch involves an active motor component—stroking, tapping, grasping, or pressing—whereby a part of the body is moved against another surface or organism. The sensory and motor components of touch are intimately connected anatomically in the brain and are important in guiding behavior.

Exteroception also includes the thermal senses of heat and cold. Thermal sensations are important controllers of behavior and homeostatic mechanisms needed to maintain the body temperature near 37°C (98.6°F). Finally,

exteroception includes the sense of pain, or nociception, a response to external events that damage or harm the body. Nociception is a prime motivator of actions necessary for survival, such as withdrawal or combat.

The third component of somatic sensation, *interoception*, is the sense of the function of the major organ systems of the body and its internal state. Although most of the events recorded by receptors in the viscera do not become conscious sensations, the information conveyed by these receptors is crucial for regulating autonomic functions, particularly in the cardiovascular, respiratory, digestive, and renal systems. Interoceptors are primarily chemoreceptors that monitor organ function through such indicators as blood gases and pH.

Abnormal function in major organ systems resulting from disease or trauma can evoke conscious sensations of pain. Much of our knowledge of the neural mechanisms of pain is derived from studies of cutaneous nociceptors because the mechanisms are easier to study in cutaneous nerves than in visceral nerves. Nevertheless, the neural mechanisms underlying visceral pain are similar to those for pain arising from the surface of the body.

This diverse group of sensory functions may seem an unlikely combination to form a sensory system. We treat all of the somatic senses in one introductory chapter because they are mediated by one class of sensory neurons, the dorsal root ganglion neurons. Individual neurons in a dorsal root ganglion respond selectively to specific types of stimuli because of morphological and molecular specialization of their peripheral terminals.

In this chapter we consider the principles common to all dorsal root ganglion neurons and those that distinguish their individual sensory function. We begin with a description of the peripheral nerves and their organization, followed by a survey of the receptors responsible for each of the major bodily senses. We then consider their sensory pathways in the spinal cord and brain stem. The chapter concludes with a discussion of the central processing centers for each submodality in the thalamus. The physiological function of touch, pain, proprioception, and autonomic regulation are described in more detail in separate chapters.

The Primary Sensory Neurons of the Somatosensory System Are Clustered in the Dorsal Root Ganglia

Somatosensory information from the skin, muscles, joint capsules, and viscera is conveyed by dorsal root

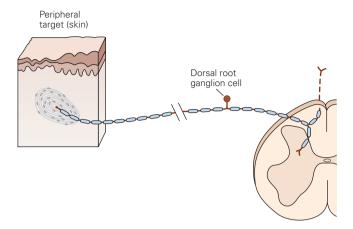

Figure 22–1 The dorsal root ganglion neuron is the primary sensory receptor cell of the somatosensory system. The neuron cell body is located in a dorsal root ganglion adjacent to the spinal cord. The axon has two branches, one projecting to the periphery, where its specialized terminal contains receptors for a particular form of stimulus energy, and one projecting to the spinal cord or brain stem, where the afferent signals are processed.

ganglion neurons innervating the limbs and trunk or by trigeminal sensory neurons that innervate cranial structures (the face, lips, oral cavity, conjunctiva, and dura mater). These sensory neurons perform two major functions: the transduction and encoding of stimuli into electrical signals and the transmission of those signals to the central nervous system.

The cell body of a dorsal root ganglion neuron lies in a ganglion on the dorsal root of a spinal or cranial nerve. Dorsal root ganglion neurons originate from the neural crest and are intimately associated with the nearby segment of the spinal cord.

Dorsal root ganglion neurons are a type of bipolar cell, called pseudo-unipolar cells. The axon of a dorsal root ganglion neuron has two branches, one projecting to the periphery and one projecting to the central nervous system (Figure 22–1). The peripheral terminals of different neurons innervate the skin, muscle, joint capsules, or viscera and contain receptors specialized for particular kinds of stimuli. They differ in receptor morphology and stimulus selectivity. The central branches terminate in the spinal cord or brain stem, forming the first synapses in somatosensory pathways. Thus the axon of each dorsal root ganglion cell serves as a single transmission line with one polarity between the receptor terminal and the central nervous system. This axon is called the *primary afferent fiber*.

Individual primary afferent fibers innervating a particular region of the body, such as the thumb or fingers, are grouped together into bundles or fascicles of axons forming the *peripheral nerves*. They are guided during development to a specific location in the body by various trophic factors. The peripheral nerves also include motor axons innervating nearby muscles, blood vessels, glands, or viscera.

Damage to peripheral nerves or their targets in the brain may produce sensory deficits in more than one somatosensory submodality. Knowledge of where somatosensory modalities overlap morphologically, and where they diverge, facilitates diagnosis of neurological disorders and malfunction.

Peripheral Somatosensory Nerve Fibers Conduct Action Potentials at Different Rates

The diverse modalities of somatic sensation are mediated by peripheral nerve fibers that differ in diameter and conduction velocity. Mechanoreceptors for touch and proprioception are innervated by dorsal root ganglion neurons with large-diameter, myelinated axons that conduct action potentials rapidly. Thermal receptors, nociceptors, and other chemoreceptors have small-diameter axons that are either unmyelinated or thinly myelinated; these nerves conduct impulses more slowly. The difference in conduction velocity allows signals of touch and proprioception to reach the spinal cord and higher brain centers sooner than noxious or thermal signals.

Large-diameter fibers conduct action potentials more rapidly because the internal resistance to current flow along the axon is low, and the nodes of Ranvier are widely spaced along its length (see Chapter 6). The conduction velocity of large myelinated fibers (in meters per second) is approximately six times the axon diameter (in micrometers),

whereas thinly myelinated fibers conduct at five times the axon diameter. For unmyelinated fibers, the factor for converting axon diameter to conduction velocity is 1.5 to 2.5.

Peripheral nerve fibers are classified into functional groups based on properties related to axon diameter and myelination, conduction velocity, and whether they are sensory or motor. The first classification scheme was devised in 1894 by Charles Sherrington, who measured the diameter of myelinstained axons in sensory nerves, and subsequently codified by David Lloyd (Table 22-1). They found two or three overlapping groups of axonal diameters (Figure 22–2). It was later discovered that in muscle nerves these anatomical groupings are functionally important. Group I axons innervate muscle-spindle receptors and Golgi tendon organs, which signal muscle length and contractile force. Group II fibers innervate secondary spindle endings and receptors in joint capsules; these receptors also mediate proprioception. Group III fibers, the smallest myelinated muscle afferents, and the unmyelinated group IV afferents signal disorders in muscles and joints that can be sensed as painful.

Cutaneous nerves contain two sets of myelinated fibers: Group II fibers innervate cutaneous mechanoreceptors that respond to touch, and group III fibers mediate thermal and noxious stimuli. Unmyelinated group IV cutaneous afferents, like those in muscle, also mediate thermal and noxious stimuli.

Another method for classifying peripheral nerve fibers is based on electrical stimulation of whole nerves. In this widely used diagnostic technique nerve conduction velocities are measured between pairs of stimulating and recording electrodes placed on the skin above a peripheral nerve. When studying conduction in the median or ulnar nerve, for example, the stimulation electrode might be placed on the wrist and

	Muscle nerve	Cutaneous nerve ²	Fiber diameter (µm)	Conduction velocity (m/s)
Myolinatad				
Myelinated Large diameter	I	Αα	12–20	72–120
Medium diameter	II	Αβ	6–12	36–72
Small diameter	III	Aδ	1–6	4–36
Unmyelinated	IV	С	0.2-1.5	0.4–2.0

¹Sensory fibers from muscle are classified according to their diameter, whereas those from the skin are classified by conduction velocity.

²The types of receptors innervated by each type of fiber are listed in Table 22–2.

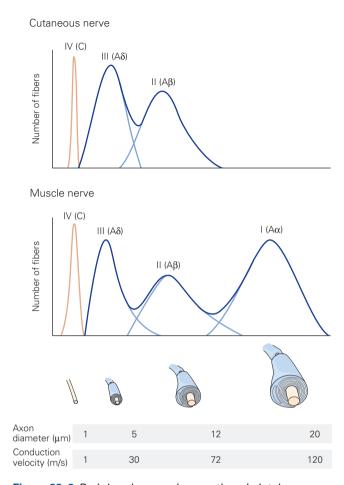

Figure 22–2 Peripheral nerves innervating skeletal muscle and the skin contain several types of sensory nerve fibers. The graphs illustrate the distribution of four groups of sensory nerve fibers innervating skeletal muscle and the skin. Each group has a characteristic axon diameter and conduction velocity. Light blue lines are the sum of fibers in each group in the zones of overlap. The conduction velocity of myelinated peripheral nerve fibers is approximately six times the fiber diameter. (Adapted, with permission, from Boyd and Davey 1968.)

the recording electrode on the upper arm. Brief electrical pulses applied through the stimulating electrode evoke action potentials in the nerve that are recorded a short time later in the arm. The recorded signal represents the summed action potentials of all of the nerve fibers excited by the stimulus pulse and is called the *compound action potential*. It increases in amplitude as more nerve fibers are stimulated; the summed activity is roughly proportional to the total number of active nerve fibers.

Electrical stimuli of increasing strength evoke action potentials in the largest axons first, for they have the lowest electrical resistance, and then in progressively smaller axons. The earliest signal recorded in the compound action potential occurs in fibers with conduction velocities greater than 90 m/s. Called the A α wave (Figure 22–3), this signal reflects the action potentials generated in group I fibers and in motor neurons innervating skeletal muscle. The sensation is barely perceived by the subject in the region innervated.

A second signal, the $A\beta$ wave, appears as more large fibers are recruited. This component corresponds to group II fibers in skin or muscle nerves and becomes larger as the shock intensity is increased. At higher voltages, when axons in the smaller $A\delta$ range are recruited, the stimulus becomes painful, resembling an electric shock produced by static electricity. Voltages sufficient to activate unmyelinated C fibers evoke sensations of burning pain. Stimulation of motor neurons innervating muscle spindles evoke an intermediate wavelet called the $A\gamma$ wave, but this is usually difficult to discern because the conduction velocities of these motor neurons overlap those of $A\beta$ and $A\delta$ sensory axons.

The clinician takes advantage of the known distribution of the conduction velocities of afferent fibers in peripheral nerves to diagnose diseases that result in sensory-fiber degeneration or motor neuron loss. In certain conditions the loss of axons is selective; in the neuropathy characteristic of diabetes, for example, the large-diameter sensory fibers degenerate. Such a selective loss is reflected in a reduction in the appropriate peak of the compound action potential, a slowing of nerve conduction, and a corresponding diminution of sensory capacity. Similarly, in multiple sclerosis the myelin sheath of large-diameter fibers in the central nervous system degenerates, producing slowing of nerve conduction or failure of impulse transmission.

Rapid conduction in a peripheral nerve axon solves two problems. First, it provides the prompt sensory feedback required for motor control. The greatest velocities are in the afferent fibers from muscle that signal muscle length, contraction velocity, and force. Any delay in the feedback signal would cause instability, which probably explains why the fibers innervating spindles have the greatest diameters among peripheral axons.

Conduction-delay dispersion poses a second significant problem because conduction velocity varies among afferent fibers. Synchronous firing of a set of neurons becomes desynchronized by the time the action potentials reach the postsynaptic cells by an amount that is proportional to the mean conduction delay and the variation in conduction velocities. If the delay is great, either because the pathway is long or

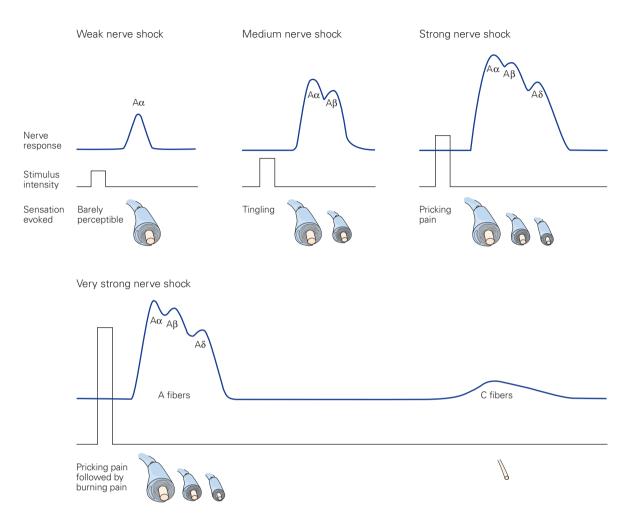

Figure 22–3 Conduction velocities of peripheral nerves are measured clinically from compound action potentials. Electrical stimulation of a peripheral nerve at varying intensities activates different types of nerve fibers. The action potentials of all the nerves stimulated by a particular amount of current are

summed to create the compound action potential. The distinct conduction velocities of different classes of sensory and motor axons produce multiple deflections. (Adapted, with permission, from Erlanger and Gasser 1938.)

because the conduction velocities are low, the desynchronization can be substantial.

As a general rule, conduction velocity throughout the nervous system is correlated with the need to maintain synchrony. The disparity in conduction times from a fingertip to the spinal cord can be calculated from the conduction velocities in Table 22–1 and by considering that the distance is approximately 0.8 m. In C fibers delays range from 0.8 s to 1.8 s, the mean delay is about 1.3 s, and the spike arrival times are distributed over about 1 s; thus events occurring more often than once per second are smeared together. In $A\alpha$ fibers delays range from 7.5 ms to 12.5 ms, the mean delay is 10 ms, and the arrival times vary by only 5 ms; events can therefore occur as often as 200 per second without smearing.

The comparable limits for $A\delta$ and $A\beta$ fibers are approximately 8 Hz and 80 Hz. A blind person can scan his or her fingers across Braille dot patterns at remarkable rates of up to 100 mm/s with little loss of information because tactile information is conveyed by $A\beta$ afferents, which maintain synchrony to within 12 ms.

Many Specialized Receptors Are Employed by the Somatosensory System

The particular receptor class expressed in the nerve terminal of a sensory neuron determines the type of stimulus detected by the neuron. The peripheral axons of the sensory neurons that mediate touch and proprioception terminate in a nonneural capsule. They sense mechanical stimuli that indent or otherwise physically deform the receptive surface. In contrast the peripheral axons of neurons that detect noxious, thermal, or chemical events have unsheathed endings with multiple branches.

When a somatic receptor is activated by an appropriate stimulus, the terminal of the sensory neuron is typically depolarized. Stimuli of sufficient strength produce action potentials that are transmitted along the peripheral branch of the neuron's axon and into the central branch that terminates in the spinal cord or brain stem.

A variety of morphologically specialized receptors underlie the various somatosensory submodalities. For example, the median nerve that innervates the skin of the hand and some of the muscles controlling the hand contains tens of thousands of nerve fibers that can be classified into 30 functional types. Of these, 22 types are afferent fibers (sensory axons conducting

impulses toward the spinal cord), and eight types are efferent fibers (motor axons conducting impulses away from the spinal cord to skeletal muscle, blood vessels, and sweat glands). The afferent fibers convey signals from eight kinds of cutaneous mechanoreceptors that are sensitive to different kinds of skin deformation; five kinds of proprioceptors that signal information about muscle force, muscle length, and joint angle; four thermoreceptors that report the temperatures of objects touching the skin; four nociceptors that signal potentially injurious stimuli; and at least one kind of itch receptor. The major receptor groups within each submodality are listed in Table 22–2.

Mechanoreceptors Mediate Touch and Proprioception

Mechanoreceptors sense physical deformation of the tissue in which they reside. Mechanical distension,

Table 22–2 Receptor Types Active in Somatic Sensation

Receptor type	Fiber group ¹	Fiber name	Modality
Cutaneous and subcutaneous mechanoreceptors			Touch
Meissner corpuscle	Αα,β	RA1	Stroking, flutter
Merkel disk receptor	Αα,β	SA1	Pressure, texture
Pacinian corpuscle ²	Αα,β	RA2	Vibration
Ruffini ending	Αα,β	SA2	Skin stretch
Hair-tylotrich, hair-guard	Αα,β	G1, G2	Stroking, fluttering
Hair-down	Αδ	D	Light stroking
Field	Αα,β	F	Skin stretch
C mechanoreceptor	C		Stroking, erotic touch
Thermal receptors			Temperature
Cool receptors	Αδ	III	Skin cooling (<25°C [77°F])
Warm receptors	C	IV	Skin warming (>35°C [95°F])
Heat nociceptors	Αδ	III	Hot temperature (>45°C [113°F])
Cold nociceptors	C	IV	Cold temperature (<5°C [41°F])
Nociceptors			Pain
Mechanical	Αδ	III	Sharp, pricking pain
Thermal-mechanical (heat)	Αδ	III	Burning pain
Thermal-mechanical (cold)	C	IV	Freezing pain
Polymodal	C	IV	Slow, burning pain
Muscle and skeletal mechanoreceptors			Limb proprioception
Muscle spindle primary	Αα	Ia	Muscle length and speed
Muscle spindle secondary	Αβ	II	Muscle stretch
Golgi tendon organ	Αα	Ib	Muscle contraction
Joint capsule receptors	Αβ	II	Joint angle
Stretch-sensitive free endings	Αδ	III	Excess stretch or force

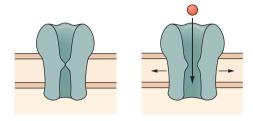

¹See Table 22-1

²Pacinian corpuscles are also located in the mesentery, between layers of muscle, and on interosseous membranes.

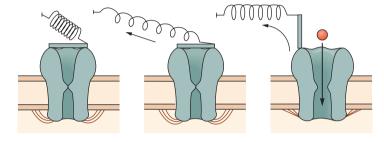

Figure 22–4 Ion channels in mechanoreceptor nerve terminals are activated by mechanical stimuli that stretch or deform the cell membrane. Mechanical displacement leads to channel opening, permitting the influx of cations. (Modified, with permission, from Lin and Corey 2005.)

- A. Channels can be directly activated by forces conveyed through lipid tension in the cell membrane, such as osmotic swelling.
- B. Forces conveyed through structural proteins linked to the ion channel can also directly activate channels. The linking proteins may be either extracellular (attached to the surrounding tissue) or intracellular (bound to the cytoskeleton) or both.
- **C.** Channels can be indirectly activated by forces conveyed to a force sensor (a separate protein) in the membrane. An internal second messenger carries the sensory signal from the mechanosensitive protein to the channel.

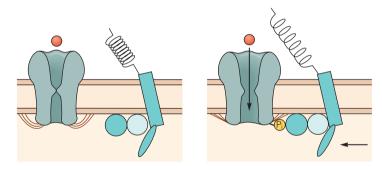

A Direct activation through lipid tension

B Direct activation through structural proteins

C Indirect action through membrane structural proteins

such as pressure on the skin or stretch of muscles, is transduced into electrical energy by the physical action of the stimulus on cation channels in the membrane. Mechanical stimulation deforms the receptor protein, thus opening stretch-sensitive ion channels and increasing Na⁺ and Ca²⁺ conductances that depolarize the receptor neuron. Removal of the stimulus relieves mechanical stress on the receptor and allows stretch-sensitive channels to close.

Some mechanoreceptor ion channels are activated directly by forces applied to the tissue, permitting rapid activation and inactivation. For example, Pacinian corpuscle receptors in the skin can respond to vibration at frequencies as high as 500 Hz, firing one impulse for each vibratory cycle. This means that the receptor is capable of firing an impulse every 2 ms for sustained periods.

Various mechanisms for direct activation of mechanoreceptor ion channels have been proposed. Some mechanoreceptors appear to respond to forces conveyed through tension in the lipids of the plasma membrane (Figure 22–4A). This may be the mechanism for detection of cellular swelling, which plays an important role in osmoregulation.

Another mechanism for direct activation of mechanoreceptors is linking the channel to the surrounding tissue of the skin or to muscle cell membranes through structural proteins. The extracellular linkage is elastic and often represented as a spring, whereas the intracellular portion of the channel is anchored directly to proteins of the cytoskeleton (Figure 22–4B). Direct channel gating in this model may be produced by forces perpendicular or parallel to the receptor cell membrane that stretch the extracellular linkage protein.

This type of direct channel gating may be used by hair cells of the inner ear. Similar mechanical linkages between the skin and cutaneous mechanoreceptors have been postulated.

Likewise, mechanical coupling of sensory nerve terminals to skeletal muscle or tendons is thought to underlie proprioception. Unfortunately, because these receptors are embedded in nonneural tissue and thus difficult to isolate for biochemical analysis, the proteins involved in transduction have not been identified in mammals. Studies of invertebrates suggest that the transduction molecules for mechanosensation in skin and muscle may belong to the degenerin superfamily, which includes ion channels related to vertebrate epithelial Na⁺ channels.

Some mechanoreceptor ion channels are activated indirectly through second-messenger pathways. In this case the force sensor in the receptor's cell membrane is a protein distinct from the ion channel (Figure 22-4C). A variety of intracellular messengers signal stimulation of the sensor to the ion channel, causing the channel to open. Unlike direct activation, the indirect pathway is slow to activate and inactivate, often outlasting the stimulus. The great advantage of the second-messenger mechanism of course is that the sensory signal is amplified; the conductance of many ionic channels can be affected by the activation of a single sensor molecule in the receptor cell. These properties are consistent with the responses of pain receptors sensitive to mechanical damage of the skin, such as pinch, or excessive distension of viscera. David Corey and co-workers have suggested that these sensations are mediated by TRPV4 receptors, a class of transient receptor potential (TRP) receptors that are also involved in thermal senses (see below).

The specialized, nonneural end organ that surrounds the nerve terminal of a mechanoreceptor nerve must be deformed in specific ways to excite the nerve. For example, individual receptors may respond selectively to pressure or motion, and may detect the direction of force applied to the skin, joints, or muscle fibers. The end organ can also amplify or modulate the sensitivity of the receptor to mechanical displacement.

The skin has eight types of mechanoreceptors that are responsible for the sense of touch (see Table 22–2). They are described briefly here and in greater detail in Chapter 23. The glabrous skin of the hands and feet contains four kinds of mechanoreceptors: Meissner corpuscles, Merkel cells, Pacinian corpuscles, and Ruffini endings (Figure 22–5). Two of these receptors are classified as slowly adapting (SA) because they continue to fire in response to steady pressure on the skin. The other two receptors are rapidly adapting (RA), responding to

motion on the skin but not to steady pressure. They also differ in receptor size and location within the skin.

Merkel cells are innervated by slowly adapting type 1 (SA1) fibers. They signal the amount of pressure applied to the skin and are particularly sensitive to edges, corners, and points. They distinguish textures and play key roles in the ability to read Braille. The Ruffini endings are innervated by slowly adapting type 2 (SA2) fibers. These receptors respond more vigorously to stretch than to indentation of skin, and consequently are particularly sensitive to the shape of large objects held in the hand. They also signal movements of the fingers and other joints that stretch the overlying skin.

Meissner corpuscles are innervated by rapidly adapting type 1 (RA1) fibers. These receptors detect the initial contact of the hand with objects, slippage of objects held in the hand, motion of the hand over textured surfaces, and low-frequency vibration. The Pacinian corpuscles are innervated by rapidly adapting type 2 (RA2) fibers. The receptor is a large, onion-like capsule that surrounds the axon terminal. It responds to motion in the nanometer range and mediates high-frequency vibration. The most important role of Pacinian corpuscles is detection of vibrations in tools, objects, or probes held in the hand.

The general hairy skin includes all of the mechanoreceptor organs of the glabrous skin except the Meissner corpuscle; the hair follicle afferents serve a function similar to that of Meissner corpuscles. Hair follicle afferents innervate 10 to 30 hairs spread over an area of 1 to 2 cm² and are sensitive to hair movement but not to static pressure. Other mechanoreceptors of the hairy skin include field receptors, which are very sensitive to skin movement, and low-threshold mechanoreceptors innervated by C fibers that respond to slow stroking of the skin and are thought to mediate erotic touch.

Proprioceptors Measure Muscle Activity and Joint Positions

Mechanoreceptors in muscles and joints convey information about the posture and movements of the body and thereby play an important role in proprioception and motor control. These receptors include two types of muscle-length sensors, the type Ia and II muscle-spindle endings; one muscle force sensor, the Golgi tendon organ; and joint-capsule receptors, which transduce tension in the joint capsule.

The muscle spindle consists of a bundle of thin muscle fibers, or intrafusal fibers, that are aligned parallel to the larger fibers of the muscle and enclosed within a capsule (Figure 22–6A). The intrafusal fibers

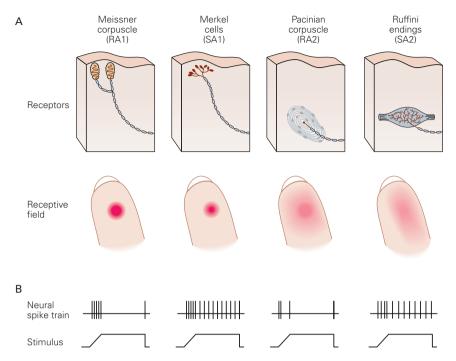

Figure 22–5 Touch is mediated by four types of mechanoreceptors in the human hand. The terminals of myelinated sensory nerves innervating the hand are surrounded by specialized structures that detect contact on the skin. The receptors differ in morphology, innervation patterns, location in the skin, receptive field size, and physiological responses to touch. (Adapted, with permission, from Johansson and Vallbo 1983.)

A. The superficial and deep layers of the glabrous (hairless) skin of the hand each contain distinct types of mechanoreceptors. The superficial layers contain small receptor cells: Meissner corpuscles and Merkel cells. The sensory nerve fibers innervating these receptors have branching terminals such that each fiber innervates multiple receptors of one type. The deep layers of the skin and subcutaneous tissue contain large receptors: Pacinian corpuscles and Ruffini endings. Each of these receptors

is innervated by a single nerve fiber, and each fiber innervates only one receptor. The receptive field of a mechanoreceptor reflects the location and distribution of its terminals in the skin. Touch receptors in the superficial layers of the skin have smaller receptive fields than those in the deep layers. (RA1, rapidly adapting type 1; RA2, rapidly adapting type 2; SA1, slowly adapting type 1; SA2, slowly adapting type 2.)

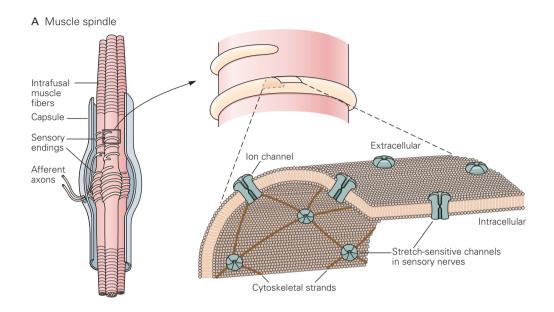

B. The nerve fibers innervating each type of mechanoreceptor respond differently when activated. The spike trains show responses of each type of nerve when its receptor is activated by constant pressure against the skin. The RA type fibers that innervate Meissner and Pacinian corpuscles adapt rapidly to constant stimulation while the SA type nerves that innervate Merkel cells and Ruffini endings adapt slowly.

are entwined by a pair of sensory axons that detect muscle stretch because of mechanoreceptive ion channels in the nerve terminals. Intrafusal muscles are also innervated by motor neurons that determine contractile force. (See Box 35–1 for details on muscle spindles.)

Although the receptor potential and firing rates of the sensory axons are proportional to muscle length (Figure 22–6B), these responses can be modulated by higher centers in the brain that regulate contraction of intrafusal muscles. In this manner the spindle afferents are able to signal the amplitude and speed of internally generated voluntary movements as well as passive limb displacement by external forces.

Golgi tendon organs, located between skeletal muscle and tendons, measure the forces generated by muscle contraction. (See Box 35–3 for details on Golgi tendon organs.) Although these receptors play an important role in reflex circuits modulating muscle force, they appear to contribute little to conscious sensations of muscle activity. Psychophysical experiments in which muscles are fatigued or partially paralyzed have shown that perceived muscle force is mainly related to centrally generated effort rather than to actual muscle force.

Joint receptors play little if any role in postural sensations of joint angle. Instead, the perception of the angle of proximal joints such as the elbow or knee depends on afferent signals from muscle spindle receptors and efferent motor commands. Likewise, conscious sensations of finger position and hand shape

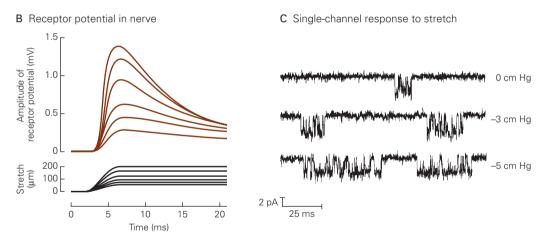

Figure 22–6 The muscle spindle is the principal receptor mediating proprioception.

A. The muscle spindle is located within skeletal muscle and is excited by stretch of the muscle. It consists of a bundle of thin (intrafusal) muscle fibers entwined by a pair of sensory axons, and is also innervated by several motor axons (not shown) that produce contraction of the intrafusal muscle fibers. Stretch-sensitive ion channels in the sensory nerve terminals are linked to the cytoskeleton by the protein spectrin. (Adapted, with permission, from Sachs 1990.)

B. The depolarizing receptor potential recorded in a group la fiber innervating the muscle spindle (**upper record**) is proportional to both the velocity and amplitude of muscle stretch

parallel to the myofilaments (**lower record**). When stretch is maintained at a fixed length, the receptor potential decays to a lower value. (Adapted, with permission, from Ottoson and Shepherd 1971.)

C. Patch clamp recordings of a single stretch-sensitive channel in myocytes. Pressure is applied to the receptor cell membrane by suction. At rest (top record) the channel opens sporadically for short time intervals. As the pressure applied to the membrane increases (lower records) the channel opens more often and remains in the open state longer. This allows more current to flow into the receptor cell, resulting in higher levels of depolarization. (Adapted, with permission, from Sachs 1990.)

depend on stretch receptors in the skin as well as muscle spindles and possibly joint receptors.

Nociceptors Mediate Pain

The receptors that respond selectively to stimuli that can damage tissue are called *nociceptors* (Latin *nocere*, to injure). They respond directly to mechanical and thermal stimuli, and indirectly to other stimuli by means of chemicals released from cells in the traumatized tissue. Nociceptors signal impending tissue injury and, more importantly, they provide a constant reminder of tissues that are already injured and must be protected.

Nociceptors in the skin, muscle, joints, and visceral receptors fall into two broad classes based on the myelination of their afferent fibers. Nociceptors innervated by $A\delta$ fibers produce short-latency pain that is described as sharp and pricking. The majority are called mechanical nociceptors because they are excited by sharp objects that penetrate, squeeze, or pinch the skin (Figure 22–7). Many of these $A\delta$ fibers also respond to noxious heat that can burn the skin.

Nociceptors innervated by C fibers produce dull, burning pain that is diffusely localized and poorly tolerated. The most common type are polymodal nociceptors that respond to a variety of noxious mechanical, thermal, and chemical stimuli, such as pinch or puncture, noxious heat and cold, and irritant chemicals applied to the skin. Electrical stimulation of these fibers in humans evokes prolonged sensations of burning pain. In the viscera nociceptors are activated by distension or swelling, producing sensations of intense pain.

Thermal Receptors Detect Changes in Skin Temperature

Although the size, shape, and texture of objects held in the hand can be apprehended visually as well as by touch, the thermal qualities of objects are uniquely somatosensory. Humans recognize four distinct types of thermal sensation: cold, cool, warm, and hot. These sensations result from differences between the external temperature of the air or of objects contacting the body and the normal skin temperature of approximately 32°C (90°F).

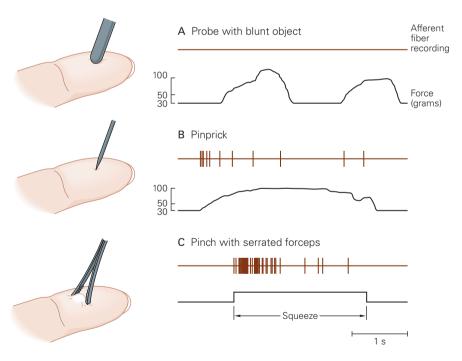

Figure 22–7 Mechanical nociceptors respond to stimuli that puncture, squeeze, or pinch the skin. Sensations of sharp, pricking pain result from stimulation of $A\delta$ fibers with free nerve endings in the skin. These receptors respond to sharp objects that puncture the skin (B) but not to strong pressure

from a blunt probe (A). The strongest responses are produced by pinching the skin with serrated forceps that damage the tissue in the region of contact (C). (Adapted, with permission, from Perl 1968.)

Although we are exquisitely sensitive to sudden changes in skin temperature, we are normally unaware of the wide swings in skin temperature that occur as our cutaneous blood vessels open and close to discharge or conserve body heat. If skin temperature changes slowly, we are unaware of changes in the range 31° to 36°C (88–97°F). Below 31°C (88°F) the sensation progresses from cool to cold and finally, beginning at 10° to 15°C (50–59°F), to pain. Above 36°C (97°F) the sensation progresses from warm to hot and then, beginning at 45°C (113°F), to pain.

Thermal sensations result from the combined activity of six types of afferent fibers: low-threshold and high-threshold cold receptors, warm receptors, and two classes of heat nociceptors. The low-threshold cold receptor fibers are small-diameter, myelinated A δ fibers with unmyelinated endings within the epidermis. They are approximately 100 times more sensitive to sudden drops in skin temperature than to gradual changes. This extreme sensitivity to change allows humans to detect a draft from a distant open window. The high-threshold cold receptor fibers are much less sensitive to small cooling changes, but can signal rapid skin cooling even below 0°C (32°F).

The various qualities of cold sensations can be experienced by grasping an ice cube in a closed fist. Over the first five seconds or so the sensation progresses from cool to cold. After 10 seconds the sensation becomes progressively more painful. If the ice is held still longer, the sensation begins to include a deep, aching quality. The low-threshold and high-threshold receptors account for the initial sensations; the aching cold pain likely results from receptors within the veins.

Warm receptors are located in the terminals of C fibers that end in the dermis. Unlike the cold receptors, warm receptors act more like simple thermometers; their firing rates rise monotonically with increasing skin temperature up to the threshold of pain and then saturate at higher temperatures. Thus they cannot play a role in signaling heat pain. They are much less sensitive to rapid changes in skin temperature than are cold receptors. Consequently, humans are less responsive to warming than cooling; the threshold for detecting sudden skin warming, even in the most sensitive subject, is about 0.1 Centigrade degree.

Heat nociceptors are activated by temperatures exceeding 45°C (113°F) and inactivated by skin cooling. The burning pain caused by high temperatures is transmitted by both myelinated A δ fibers and unmyelinated C fibers.

Recent studies by David Julius and his colleagues revealed that thermal stimuli activate specific classes of TRP ion channels in the membrane. These nonselective cation receptor-channels are similar in structure to voltage-gated channels. They have four protein subunits, each of which contains six transmembrane domains, with a pore between the fifth and sixth segments. Both the C and N terminals are located in the cytoplasm. Individual TRP receptor-channels are distinguished by their sensitivity to heat or cold, showing sharp increases in conductance to cations when their thermal threshold is exceeded (Figure 22–8). Their names specify the genetic subfamily of TRP receptors and the member number. Examples include TRPV1 (for TRP vanilloid-1), TRPM8 (for TRP melastatin-8), and TRPA1 (for TRP ankyrin-1).

Two classes of TRP receptors are activated by cold temperatures and inactivated by warming. TRPM8 receptors respond to temperatures below 25°C (77°F); such temperatures are perceived as cool or cold. TRPA1 receptors have thresholds below 17°C (63°F); this range is described as cold or frigid. Both TRPM8 and TRPA1 receptors are expressed in high-threshold cold receptor terminals, but only TRPM8 receptors are expressed in low-threshold cold receptor terminals.

Four types of TRP receptors are activated by warm or hot temperatures and inactivated by cooling. TRPV3 receptors are expressed in warm type fibers; they respond to warming of the skin above 35°C (95°F) and generate sensations ranging from warm to hot. TRPV1 and TRPV2 receptors respond to temperatures exceeding 45°C (113°F) and mediate sensations of burning pain; they are expressed in heat nociceptors. TRPV4 receptors are activated by temperatures above 27°C and respond to normal skin temperatures. They may play a role in touch sensation.

The role of TRP receptors in thermal sensation was originally discovered by analyses of natural substances such as capsaicin and menthol that produce burning or cooling sensations when applied to the skin or injected subcutaneously. Capsaicin, the active ingredient in chili peppers, has been used extensively to activate nociceptive afferents that mediate sensations of burning pain. These studies indicate that the various TRP receptors also bind other molecules that induce painful sensations, such as toxins, venoms, and substances released by diseased or injured tissue. These substances act by covalent modification of cysteines in the TRP channel protein.

Itch Is a Distinctive Cutaneous Sensation

Itch is a common sensory experience that is confined to the skin, the ocular conjunctiva, and the mucosa. Itch has some properties in common with pain and

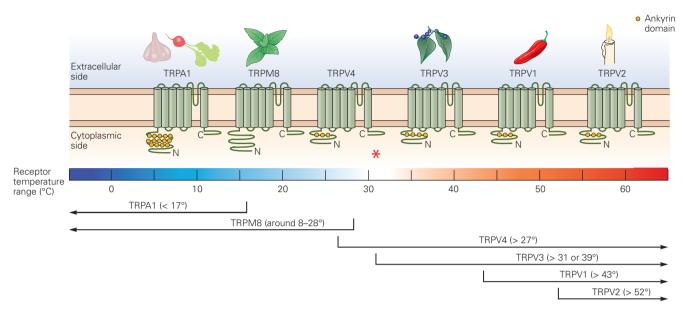

Figure 22–8 Transient receptor potential ion channels. Transient receptor potential (TRP) channels are membrane proteins with six transmembrane domains. A pore is formed between the fifth (S5) and sixth (S6) segments. Both C- and N-terminals are located in the cytoplasm. Most of these receptors contain ankyrin repeats in the N-terminal domains and a common 25-amino acid motif adjacent to S6 in the C-terminal domain. All TRP channels are gated by temperature and various chemical ligands, but different types respond to different temperature ranges and have different activation thresholds. At least six types of TRP receptors have been identified in sensory neurons; the thermal sensitivity of a neuron is determined by the particular TRP receptors expressed in its nerve terminals.

At 32°C (90°F), the resting skin temperature (asterisk), only TRPV4 and some TRPV3 receptors are stimulated. TRPA1 and TRPM8 receptors are activated by cooling and cold stimuli. TRPM8 receptors also respond to menthol and various mints; TRPA1 receptors respond to alliums such as garlic and radishes. TRPV3 receptors are activated by warm stimuli and also bind camphor. TRPV1 and TRPV2 receptors respond to heat and produce burning pain sensations. TRPV1 but not TRPV2 receptors bind capsaicin, which mediates the burning sensations evoked by chili peppers. TRPV4 receptors are active at normal skin temperatures and respond to touch. (Adapted, with permission, from Jordt, McKemy, and Julius 2003; Dhaka, Viswanath, and Patapoutian 2006.)

until recently was thought to result from low firing rates in nociceptive fibers. Like pain, itch is inherently unpleasant whatever its intensity; even at the expense of inducing pain, we attempt to eliminate it by scratching. When nerve conduction is blocked with pressure, itch persists until the slowest unmyelinated fibers stop firing.

Itch can be induced either by the injection of histamine or by procedures that release endogenous histamine, which suggests that the transducers are coupled to histamine receptors. Intradermal injection of a large dose of histamine produces intense itch that persists for tens of minutes but only mild pain, a strong indication that itch is not the result of low-level firing in polymodal nociceptors. Instead, itch appears to be mediated by a recently discovered class of C fibers with very slow conduction velocities (0.5 m/s) and physiological properties paralleling the time course of histamine-evoked itch.

Visceral Sensations Represent the Status of Various Internal Organs

Visceral sensations are important physiologically because they drive several types of behavior that are critical for survival, such as respiration, hunger, thirst, sexual arousal, and copulation. After about a minute without breathing, hunger for air, feelings of suffocation, and the need to relieve those sensations become all-consuming behavioral goals. These sensations allow us to hold our breath when needed with the knowledge that an internal sensory signal will tell us when it is no longer safe to do so. Thirst and hunger likewise provide the motivation to drink and eat; they come to dominate our behavior when we have been without water or food for periods that threaten our survival.

Visceral sensations that are linked directly to survival result from both peripheral and central sensors. Sensations associated with the need to breathe, for

example, arise from partial pressure of oxygen (PO₂) and partial pressure of carbon dioxide (PCO₂) sensors in the carotid bodies associated with the carotid arteries and from PCO₂ receptors in the respiratory centers of the medulla and hypothalamus (see Chapter 45). Damage to these medullary centers results in a loss of air hunger (Ondine's curse) and often death from failure of automatic breathing during sleep.

Hunger arises from an interaction between signals from hypothalamic chemoreceptors that respond to a variety of molecules in the blood and signals from the gut that indicate the presence or absence of food (see Chapter 49). Thirst results from central mechanisms whose site is uncertain and from peripheral signals from osmoreceptors in the liver and stretch receptors in the cardiopulmonary blood vessels that provide information on blood volume (see Chapter 49).

Nausea, which teaches animals—including us—which foods are unsafe to eat, depends on vagal serotonin receptors in the gut as well as the area postrema in the brain stem. Neurons within the area postrema are able to sense toxins in the blood and cerebrospinal fluid because the area lacks a blood-brain barrier (see Appendix D).

Sensations associated with sexual arousal and copulation, which are essential for survival of the species, arise from low-threshold mechanoreceptors in the genitalia and other body sites. Although the central component is not certain, functional imaging studies and experimental lesion studies suggest that the preoptic area and anterior hypothalamus are important components of arousal (see Chapter 47).

Somatosensory Information Enters the Central Nervous System Through Cranial and Spinal Nerves

Sensory information reaches the central nervous system either through the 31 spinal nerves, which enter through openings between the vertebrae of the spine, or through the 12 cranial nerves, which enter through openings in the cranium. The afferent and efferent axons within a spinal nerve arise from the dorsal and ventral roots of the spinal cord (see Figure 16–3), which are arrayed more or less continuously along the dorsal and ventral surfaces of each half of the cord (see Figure 16–2). To exit between the vertebrae, the roots gather into nerves that are named for the vertebrae below the foramen through which they pass (cervical nerves) or above (thoracic, lumbar, and sacral nerves).

The skin and deeper tissues innervated by the afferent fibers of a single spinal nerve constitute a

dermatome (Figure 22–9); the muscles innervated by the same nerve constitute a *myotome*. These are the skin and muscle regions affected by damage to a single spinal nerve. Because the dermatomes overlap, three adjacent spinal nerves often have to be blocked to anesthetize a particular area of skin.

Individual spinal nerves terminate on neurons located in specific zones of the spinal cord gray matter (see Figure 16–1). The spinal neurons that receive sensory input are either interneurons, which terminate upon other spinal neurons within the same or neighboring segment, or projection neurons that serve as the cells of origin of major ascending pathways to higher centers in the brain.

All but one of the spinal nerves contain both afferent and efferent nerve fibers; the exception is C1, which usually has only efferent axons. In contrast, 8 of the 12 cranial nerves are either pure motor or pure sensory nerves serving the special senses (olfactory, optic, and vestibulocochlear). The remaining four nerves (trigeminal, facial, glossopharyngeal, and vagus) are mixed nerves that together serve the same range of bodily senses as do the spinal nerves. Like the spinal nerves, the cell bodies of cranial nerves lie in ganglia near the point of entry to the central nervous system.

Each of the mixed cranial nerves has a distinct pattern of termination within the central nervous system and each is devoted principally to sensory information either from the viscera or from the skin and muscles (see Figure 45–5). The trigeminal nerve conveys sensory information from muscles of mastication and skin on the anterior half of the head. The facial and glossopharyngeal nerves innervate the taste buds of the tongue, the skin of the ear, and some of the skin of the tongue and pharynx. The glossopharyngeal and vagus nerves provide some cutaneous information, but their main sensory role is visceral. Cutaneous and proprioceptive information from all four nerves enters the trigeminal nuclei; visceral information flows into the nucleus of the solitary tract.

Somatosensory Information Flows from the Spinal Cord to the Thalamus Through Parallel Pathways

The nerve fibers that convey the various somatosensory submodalities from each dermatome are bundled together in the peripheral nerves as they enter the dorsal root ganglia. However, as the fibers exit the ganglia and approach the spinal cord, the large- and small-diameter fibers separate into medial and lateral divisions.

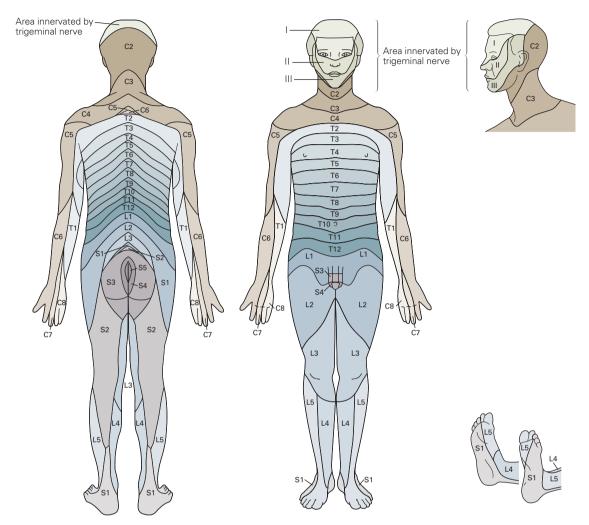

Figure 22–9 The distribution of dermatomes. A dermatome is the area of skin and deeper tissues innervated by a single dorsal root. The dermatomes of the 31 pairs of dorsal root nerves are projected onto the surface of the body and labeled by the foramen through which each nerve enters the spinal cord. The 8 cervical (C), 12 thoracic (T), 5 lumbar (L), 5 sacral (S), and single coccygeal roots are numbered rostrocaudally for each division of the vertebral column. The facial skin, cornea, scalp, dura, and intra-oral regions are innervated by the

ophthalmic (I), maxillary (II), and mandibular (III) divisions of the trigeminal nerve (cranial nerve V). Level C1 has no dorsal root, only a ventral (or motor) root. Dermatome maps provide an important diagnostic tool for locating injury to the spinal cord and dorsal roots. However, the boundaries of the dermatomes are less distinct than shown here because the axons comprising a dorsal root originate from several different peripheral nerves, and each peripheral nerve contributes fibers to several adjacent dorsal roots.

The medial division includes large, myelinated $A\alpha$ and $A\beta$ fibers that transmit proprioceptive and cutaneous information from a dermatome. The lateral division includes small thinly myelinated $A\delta$ and unmyelinated C fibers that transmit noxious, thermal, and visceral information from the same dermatome. After entering the spinal cord the afferent fibers become further segregated according to modality and terminate on different functional sets of neurons in the

gray matter of the same or adjacent spinal segments. In addition, the $A\alpha$ and $A\beta$ fibers send a major branch to the medulla through the dorsal columns.

The gray matter in each spinal segment is divided into three functionally distinct regions: the dorsal and ventral horns and an intermediate zone. As a general rule the largest fibers $(A\alpha)$ terminate in or near the ventral horn, the medium-size fibers $(A\beta)$ from the skin and muscle terminate in intermediate layers of

the dorsal horn, and the smallest fibers (A δ and C) terminate in the most dorsal portion of the spinal gray matter.

The spinal gray matter is further subdivided into 10 laminae (or layers), numbered I to X from dorsal to ventral, based on differences in cell and fiber composition. Lamina I consists of a thin layer of neurons capping the dorsal horn of the spinal cord and pars caudalis of the spinal trigeminal nucleus. Individual neurons of lamina I receive monosynaptic inputs from small myelinated fibers (A δ) or unmyelinated C fibers of a single type (Figure 22–10) and therefore transmit information about noxious, thermal, or visceral stimuli. Inputs from warm, cold, itch, and pain receptors have been identified in lamina I, and some neurons have unique cellular morphologies. Lamina I neurons generally have small receptive fields localized to one dermatome.

Neurons in laminae II and III are interneurons that receive inputs from $A\delta$ and C fibers, and make

excitatory or inhibitory connections to neurons in lamina I, IV, and V that project to higher brain centers. The dendrites of neurons in laminae III to V are the main targets of the large myelinated sensory (Aβ) fibers from cutaneous mechanoreceptors (Figure 22–10). Neurons in lamina V typically respond to more than one modality—low-threshold mechanical stimuli, visceral stimuli, or noxious stimuli—and have therefore been named *wide-dynamic-range neurons*.

Visceral C fibers have widespread projections in the spinal cord that terminate ipsilaterally in laminae I, II, V, and X; some also cross the midline and terminate in lamina V and X of the contralateral gray matter. The extensive spinal distribution of visceral C fibers appears to be responsible for the poor localization of visceral pain sensations. Afferents from the pelvic viscera make important connections to cells in the central gray matter (lamina X) of spinal segments L5 and S1. Lamina X neurons in turn project their axons along the midline of the dorsal columns to

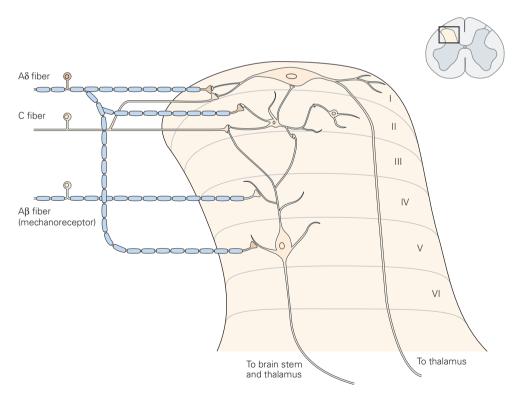

Figure 22–10 The spinal gray matter in the dorsal horn and intermediate zone is divided into six layers of cells (laminae I–VI) each with functionally distinct populations of neurons. The axons of neurons in laminae I and V make up the majority of fibers in the spinothalamic tract (see Figure 22–11). Neurons in lamina I receive nociceptive or thermal inputs from receptors

innervated by A δ or C fibers, and from interneurons in lamina II; their axons are the fastest conducting fibers in the spinothalamic tract. Neurons in lamina V respond to nociceptive and tactile information because they receive inputs from both A β and A δ fibers as well as from interneurons in laminae II, III, and IV. (Adapted, with permission, from Fields 1987.)

the nucleus gracilis in a postsynaptic dorsal column pathway for visceral pain.

Primary afferent fibers that terminate in the deepest laminae in the ventral horn feed back information from proprioceptors that is required for somatic motor control, such as spinal reflexes (see Chapter 35).

Functional separation of sensory afferents is maintained in the pathways to higher centers in the brain. Somatosensory information is conveyed to the thalamus and cerebral cortex by two ascending pathways. The dorsal column–medial lemniscal system transmits tactile and proprioceptive information, and the spinothalamic tract pain and thermal information. A third pathway, the dorsolateral tract, conveys somatosensory information from the lower half of the body to the cerebellum.

The Dorsal Column–Medial Lemniscal System Relays Tactile and Proprioceptive Information

The dorsal column on each side contains the central branches of $A\alpha$ and $A\beta$ afferents as they ascend to the medulla and thus form the major ascending pathway for tactile and proprioceptive information to the brain stem nuclei from which somatosensory information is conveyed to the cerebral cortex. They represent the most prominent anatomical feature of the dorsal funiculus of the spinal cord.

Each dorsal column is bounded medially by the median septum and laterally by the dorsal horn of the gray matter (Figure 22–11). Each contains about a million fibers as it enters the brain stem and terminates within the ipsilateral dorsal column nuclei. Of these fibers 90% are axons of dorsal root ganglion cells, and the remaining 10% are axons of spinal neurons. The postsynaptic dorsal column axons that course along the midline adjacent to the medial septum provide a specialized rapid pathway for visceral pain.

Fibers from the spinal nerves are added successively to the medial edge of the dorsal column, beginning with the fibers from the upper cervical segment and ending with the most caudal spinal nerve in the layer next to the midline. This lateral-to-medial arrangement reflects the fact that during development the most rostral spinal segments are formed earlier than the more caudal ones. In this way the dorsal column is arranged in layers, one for each dermatome. Because the dermatomes overlap extensively, adjacent layers do not convey a continuous somatotopic representation of the skin. However, when the fibers reach the brain stem they are sorted into a coherent map of the receptor sheet, with the anogenital skin of the ipsilateral side of the body most medial and the skin of the ipsilateral neck and head most lateral.

Caudal to T7 the dorsal column on each side is called the *gracile* (slender) *fascicle*. At about T7 a sulcus appears, and the remaining spinal nerves contribute to a second column called the *cuneate* (wedge-shaped) *fascicle*. The division between gracile and cuneate fascicles is important only because they terminate in anatomically distinct nuclei in the caudal brain stem, the gracile and cuneate nuclei (Figure 22–11). Together with the external cuneate nucleus and other minor nuclei, they form the dorsal column nuclei.

The gracile and cuneate nuclei are shaped like sausages with a rostrocaudal orientation. Primary afferent fibers terminate on neurons throughout the rostrocaudal extent of each nucleus so that a rod-like collection of cells extending the length of the nucleus represents one small skin region, and the neurons in any cross section represent the entire body. The somatic representation in that neural map is of a headless homunculus lying on his back with his sacrum toward the midline and his hands and feet extended dorsally. Tactile and proprioceptive information from the head, face, and mouth is represented in the adjacent principal trigeminal nucleus.

Somatosensory submodalities are segregated in the dorsal column nuclei: Individual neurons receive synaptic inputs from afferents of a single type and neurons of distinct types are spatially separated. The rostral third of the dorsal column nuclei is dominated by neurons that process proprioceptive information; nearly 75% receive sensory information from muscle afferents. Tactile inputs predominate in the middle third where nearly 90% of the neurons process cutaneous information. The neurons in the caudal third are evenly divided between cutaneous and proprioceptive modalities.

There is also a dorsal-ventral gradient both in the dorsal columns and in the dorsal column nuclei; proprioceptive neurons are more common ventrally and cutaneous neurons more common dorsally. This division may simply reflect the fact that the hands and feet, which have dense cutaneous innervation but relatively little musculature, are represented dorsally, whereas the trunk and proximal limbs, with more muscle and less skin innervation, are represented ventrally.

Lateral and rostral to the cuneate nucleus proper is the external cuneate nucleus, which receives proprioceptive afferents from the arm and hand. The external cuneate nucleus projects to both the cerebellum and thalamus.

Axons of neurons in the dorsal column nuclei form the *medial lemniscus*, which crosses the midline in the medulla and is joined medially by the homologous projection from the trigeminal nuclei (Figure 22–11). In transit the somatotopic representation becomes inverted; within the thalamus the somatotopic map displays the head medially, the sacrum laterally, and the hands and feet ventrally. Because of the crossing of the fibers in the medial lemniscus, the left side of the brain receives somatosensory input from the mechanoreceptors on the right side of the body, and vice versa.

Cutaneous information from the dorsal column and trigeminal nuclei enters the lateral and medial ventral posterior nuclei of the thalamus, which form a single functional entity. Proprioceptive information enters the superior ventral posterior nucleus, which lies just above the other two (see Figure 16–5).

The Spinothalamic System Conveys Noxious, Thermal, and Visceral Information

The *spinothalamic tract* is the principal pathway transmitting noxious, thermal, and visceral information to the thalamus and cerebral cortex (Figure 22–11). It originates from neurons in laminae I, V, and VII, the main targets of the small-diameter fibers with sensory information destined for conscious perception. These neurons have distinctive physiological properties based on their sensory inputs.

More than 50% of spinal projections to the thalamus originate from neurons in lamina I, neurons that receive inputs from nociceptors, thermal receptors, visceral afferents, or itch receptors. Lamina I has the characteristics of a modality-segregated sensory relay nucleus for somatic and visceral information transmitted by small-diameter myelinated fibers (A δ) or unmyelinated C fibers of a single type. The second major origin of fibers in the spinothalamic tract is wide-dynamic-range neurons in lamina V that respond to various combinations of tactile, visceral, thermal, and noxious stimuli.

It is reasonable to suppose, based on the neurophysiological responses of neurons in lamina I and V, that thermal sensations originate in fibers arising in lamina I whereas pain originates in fibers from either system. The pattern of sensation evoked by stimulation also reflects the projection patterns of spinothalamic tract neurons, for most but not all cross the midline to ascend in the contralateral tract (82% of the stimulus sites produced contralateral sensation, 12% ipsilateral, and 6% bilateral sensations).

The third major source of spinothalamic tract fibers is neurons in lamina VII and in deeper parts of the spinal gray matter. Lamina VII neurons receive inputs from large areas of the body, including the viscera, and therefore have very large receptive fields. This severely limits their ability to localize sensory stimuli. Further, they project to nuclei in the thalamus that are more involved in affective responses to stimuli than in identification and localization of stimuli.

The axons of most neurons in lamina I cross the midline, just ventral to the central canal, and ascend in the contralateral *lateral spinothalamic tract* located in the lateral funiculus. Axons of lamina V neurons cross the spinal cord and ascend in the contralateral *ventral spinothalamic tract*. They convey mixed information from visceroceptors, nociceptors, and low-threshold mechanoreceptors to the thalamus.

As in the medial lemniscus, fibers in the spinothalamic tract are arranged somatotopically. Fibers originating in the lumbar and sacral segments are located laterally, whereas those from the cervical spinal segments are positioned medially. The spinothalamic tract is joined by axons from the trigeminal nucleus caudalis.

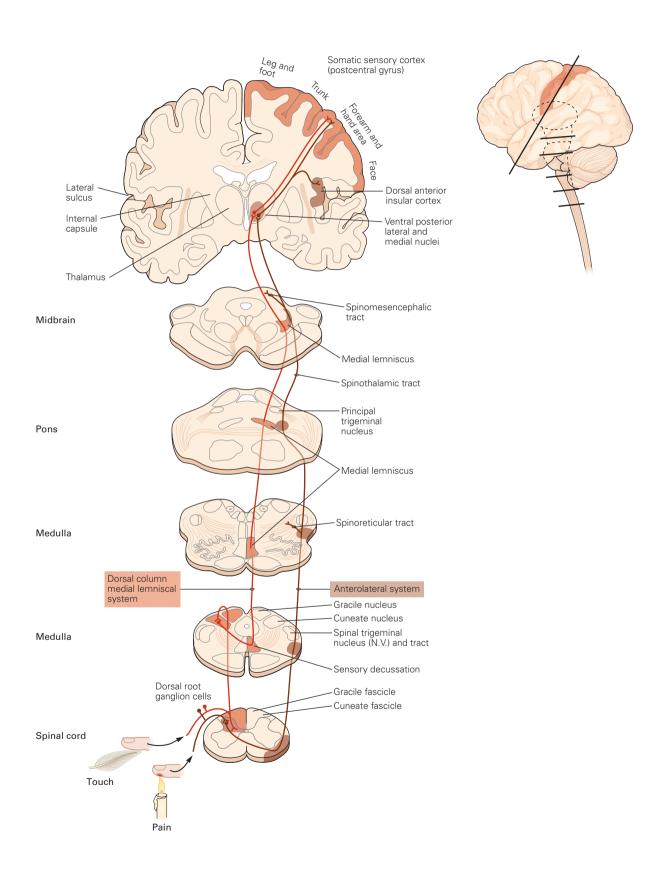

As a result of the decussation of spinothalamic fibers in the spinal cord, noxious and thermal information from each dermatome is transmitted contralaterally in the anterolateral column, whereas touch and proprioception are transmitted ipsilaterally in the dorsal column. Unilateral injury to the spinal

Figure 22–11 (Opposite) Somatosensory information from the limbs and trunk is conveyed to the thalamus and cerebral cortex by two ascending pathways. Brain slices along the neuraxis from the spinal cord to the cerebrum illustrate the anatomy of the two principal pathways conveying somatosensory information to the cerebral cortex. The two pathways are separated until they reach the pons, where they are juxtaposed.

Dorsal column—medial lemniscal system. Tactile and limb proprioception signals are conveyed to the spinal cord and brain stem by large-diameter myelinated fibers and transmitted to the thalamus in this system. In the spinal cord the fibers for touch and proprioception divide, one branch going to the spinal gray matter and the other ascending in the ipsilateral dorsal column to the medulla. The second-order fibers from

the dorsal column nuclei cross the midline in the medulla and ascend in the medial lemniscus toward the thalamus, where they terminate in the lateral and medial ventral posterior nuclei. These nuclei convey tactile and proprioceptive information to the primary somatic sensory cortex.

Anterolateral system. Pain, itch, temperature, and visceral information is conveyed to the spinal cord by small-diameter myelinated and unmyelinated fibers that terminate in the dorsal horn. This information is conveyed across the midline within the spinal cord and transmitted to the brain stem and the thalamus in the contralateral anterolateral system. Anterolateral fibers terminating in the brain stem comprise the spinoreticular and spinomesencephalic tracts; the remaining anterolateral fibers form the spinothalamic tract.

cord may therefore produce deficits in tactile and proprioceptive sensations on the same side of the body as the lesion, and impairments in thermal or painful sensations on the side opposite the lesion. The somatosensory submodalities of touch, proprioception, temperature, and pain are reunited on the contralateral side of the neuraxis higher in the brain stem as the medial lemniscus and spinothalamic tract approach the thalamus (Figure 22–11).

Information carried by small-diameter sensory fibers may also reach the cerebral cortex through several polysynaptic routes other than the spinothalamic tract. These paths include the spinomesencephalic, spinoreticular, and spinolimbic tracts that project to brain stem nuclei such as the parabrachial nucleus (Figure 22–11). These brain stem nuclei in turn project to the thalamus and to other sites that may have a sensory role, such as the hypothalamus and amygdala. Although many of these pathways originate from neurons in lamina I and V, and have physiological properties similar to spinothalamic tract neurons, they arise from a different group of neurons. Neurons that project to sites other than the thalamus may be involved in homeostasis and autonomic regulation.

Finally, as noted above, the most medial fibers in the dorsal column relay signals from nociceptors in the pelvic and abdominal viscera. We know that the postsynaptic dorsal column pathway originates with cells in the central gray matter of the sacral and midthoracic spinal cord and terminates in the gracile nucleus. Morphine infusion at these loci in animals blocks transmission of visceral pain signals. This pathway is important clinically because midline myelotomy at T10 relieves pelvic cancer pain in patients with colorectal distension.

The Thalamus Has a Number of Specialized Somatosensory Regions

The thalamus is an egg-shaped cluster of nuclei in the center of the brain that acts as a center of communication between many subcortical brain centers and the neocortex. The locations of nuclei within the thalamus correspond roughly with the hemispheric locations of the regions of the cerebral cortex with which they communicate (see Figure 16–5).

The Ventral Posterior Nucleus Relays Tactile and Proprioceptive Information

The fibers of the medial lemniscus, which convey tactile and proprioceptive signals, terminate in the ventral

posterior nucleus of the thalamus. The medial zone of the nucleus receives trigeminal nerve fibers from the head and face. The lateral zone receives fibers from the dorsal column nuclei; these inputs are arranged somatotopically, with the forelimb medial and the trunk and legs lateral. Individual body parts are represented by rod-shaped clusters of neurons aligned along the anterior-posterior axis of the thalamus.

The ventral posterior nucleus—called nucleus ventralis caudalis in humans—has traditionally been thought of as a single nucleus in which the fibers carrying cutaneous signals terminate in a large central and caudal region while those conveying proprioceptive information terminate in a dorsal and rostral region. More recently, Jon Kaas and his colleagues have argued that the two regions represent separate nuclei: the ventral posterior nucleus proper, which receives the cutaneous information conveyed by medial lemniscal and trigeminal axons, and the ventral posterior superior nucleus, which processes proprioceptive information. These nuclei send their outputs to different subregions of the cerebral cortex. The ventral posterior nucleus transmits cutaneous information primarily to area 3b of the primary somatosensory cortex, whereas the ventral posterior superior nucleus conveys proprioceptive information principally to area 3a in the postcentral gyrus. (The cortical areas for touch and proprioception are described in Chapter 23.)

Noxious, Thermal, and Visceral Information Is Processed in Several Thalamic Nuclei

The information for pain, temperature, itch, and the visceral senses takes a more complex path through the thalamus. Because virtually all of the research on this subject is concerned with the pathways for pain (see Chapter 24), inferences about the pathways for the other bodily senses relayed by the laminae I and V systems are tentative and controversial.

The axons of neurons in lamina V terminate in the ventral posterior nucleus and overlap some of the tactile inputs from the same body region. Nociceptive neurons in the nucleus project primarily to area 3a in the postcentral gyrus and are thought to play a role in localization of painful sensations.

The lamina I system terminates heavily in a concentrated region of thalamus rich in neurons that are immunoreactive to calbindin, a calcium-binding protein found in some cortical and thalamic neurons. This region spans the posterior part of the ventral posterior nucleus and the posterior part of the adjacent ventral medial nucleus. The gustatory and visceral inputs from the nucleus of the solitary tract, which terminate

in the parabrachial nuclei, also are arrayed topographically in the ventral medial nucleus.

Neurons in the ventral medial nucleus project to the insula, where they terminate in a topographic array. Functional imaging studies show that this region is a primary cortical region for thermal sensations. Because the insula also responds to visceral inputs arising from the spinal nucleus and nucleus of the solitary tract, it is sometimes called the interoceptive or visceral cortex.

An Overall View

The bodily senses mediate a wide range of experiences that are important for normal bodily function and for survival. Although diverse, they share common pathways and common principles of organization. The most important of those principles is specificity: Each of the bodily senses arises from a specific type of receptor distributed throughout the body.

Mechanoreceptors are sensitive to specific aspects of local tissue distortion, thermoreceptors to particular temperature ranges and shifts in temperature, and chemoreceptors to particular molecular structures.

The information from each type of somatosensory receptor is conveyed in discrete pathways that constitute submodalities. Information from all of the somatosensory submodalities is carried to the spinal cord or brain stem by the axons of neurons with cell bodies that generally lie in ganglia close to the point of entry. The axons are gathered together in nerves, which form the peripheral nervous system. Axon diameter and myelination, both of which determine the speed of action potential conduction, vary in different sensory pathways according to the need for speedy information.

When the axons enter the central nervous system they separate to form five separate sensory pathways with different properties. In three of those systems (the medial lemniscal, lamina I spinothalamic, and solitary tract systems) the pathways for submodalities appear to be segregated until they reach the cerebral cortex.

The medial lemniscal system includes the large myelinated axons and is organized for high-fidelity temporal and spatial information processing. Fibers from lamina I and the nucleus of the solitary tract convey information about temperature and impending and actual tissue damage, and a wide range of visceral stimuli from the small myelinated and unmyelinated axons. The lamina V spinothalamic system combines information from different submodalities at the first synapse in the pathway; the responses of neurons in lamina V correlate closely with reports of pain intensity.

The lamina VII spinothalamic system gathers information from widespread parts of the body and apparently plays a significant role in emotional responses to sensory stimuli. These afferent systems terminate in different regions of the thalamus with different functions and different cortical targets.

As described in the next few chapters, afferent nerves conveying specific somatosensory submodalities remain segregated as they reach the cerebral cortex. Information carried by large-diameter axons is conveyed to the postcentral gyrus of the neocortex and then to cortical regions concerned with motor control and cognition. Information that originated in the small-diameter axons travels to the primary somatosensory cortex but also to cortical regions concerned with autonomic functions and the emotions, such as the insula and anterior cingulate cortex.

Lesions in Somatosensory Areas of the Brain Produce Specific Tactile Deficits

An Overall View

N THIS CHAPTER ON THE SENSE OF TOUCH, we focus on the hand because of its importance in the sensory appreciation of object properties and its role in skilled

motor tasks. The hand is one of evolution's great creations. The fine manipulative capacity provided by our fingers is possible because of their fine sensory capacity; if we lose tactile sensation in our fingers we lose manual dexterity.

When we become skilled in the use of a tool, such as a scalpel or a pair of scissors, we feel conditions at the working surface of the tool as though our fingers were there because two groups of mechanoreceptors monitor the vibrations and forces produced by those distant conditions. When we scan our fingers across a surface we feel its form and texture because another group of mechanoreceptors has high spatial and temporal acuity. A blind person uses this capacity to read Braille at a hundred words per minute. When we grip and manipulate an object we do so delicately, with only as much force as is required, because yet another group of mechanoreceptors continually monitors slip and adjusts our grip appropriately.

We are also able to recognize objects placed in the hand from touch alone. When we are handed a baseball we recognize it instantly without having to look at it because of its shape, size, weight, density, and texture. We do not have to think about the information provided by each finger to deduce that the object must be a baseball; the information flows to memory and instantly matches previously stored representations of baseballs. Even if we have never previously handled a baseball, we perceive it as a single object, not as a collection of discrete features. The somatosensory pathways of the brain have the daunting task of integrating information from thousands of sensors in each hand and transforming it to a form suitable for cognition.

Sensory information is extracted for the purpose of motor control as well as cognition, and different kinds of information are extracted for those purposes. We can, for example, shift our attention from the baseball's shape to its location in the hand to readjust our grip for an effective throw. This selective attention to different aspects of the sensory information is brought about by cortical mechanisms.

Active and Passive Touch Evoke Similar Responses in Mechanoreceptors

Touch is defined as direct contact between two physical bodies. In neuroscience touch refers to the special sense by which contact with the body is perceived consciously. Touch can be active, as when you move your hand or some other part of the body against another surface, or passive, as when someone or something else touches you.

Active and passive modes of tactile stimulation excite the same population of receptors in the skin and evoke similar responses in afferent fibers. They differ somewhat in cognitive features that reflect attention and behavioral goals during the period of stimulation. Passive touch is used for naming objects or describing sensations; active touch is used when the hand manipulates objects. The sensory and motor components of touch are intimately connected anatomically in the brain and are important functionally in guiding motor behavior.

The distinction between active and passive touch is important clinically when patients have deficits in hand use. Motor deficits such as weakness, stiffness, or clumsiness may result from sensory loss, which is why passive sensory testing is important in the neurological examination (see Appendix B). Common neurological tests for touch include measurements of detection thresholds, vibration sense, two-point or texture discrimination, and the ability to recognize form through touch (stereognosis). The neural mechanisms underlying these tests are discussed in this chapter. Other common tests of somatosensory function—tendon reflexes, pinprick, and thermal tests—are discussed in other chapters.

Nearly all of these neurological tests involve passive touch; the clinician stimulates the body in a controlled and reproducible fashion. The tests measure the sensitivity and function of various receptors for touch. Deviations from the expected values may help diagnose the sensory deficits or lesions that underlie sensory dysfunction.

The Hand Has Four Types of Mechanoreceptors

The softness and compliance of the skin plays a major role in the sense of touch. When an object contacts the hand, the skin conforms to its contours, forming a mirror image of the object surface. The resultant displacement and indentation of the skin stretches the tissue, thereby stimulating the sensory endings of mechanoreceptors at or near the region of contact.

These receptors are highly sensitive and are continually active as we manipulate objects and explore the world with our hands. They provide information to the brain about the position of the stimulus on the skin, its shape and surface texture, the amount of force applied at the contact point, and how these features change over time when the hand or the object moves.

Tactile sensations in the human hand arise from four kinds of mechanoreceptors: Meissner corpuscles, Merkel cells, Pacinian corpuscles, and Ruffini endings (Figure 23–1). The sense of touch can be understood as the combined result of the information provided by these four systems acting in concert.

Each receptor responds in a distinctive manner depending on its morphology, innervation pattern, and depth in the skin. Receptors are innervated by either slowly adapting or rapidly adapting axons. Slowly adapting (SA) fibers respond to steady skin indentation with a sustained discharge, whereas rapidly adapting (RA) fibers stop firing as soon as the indentation is stationary. Sustained mechanical sensations from the hand must accordingly arise from the SA fibers. The sensation of motion across the skin is signaled by RA fibers. The receptors are further subdivided into two types based on size and location in the skin; each type includes both rapidly and slowly adapting fibers.

Thus tactile sensation in the hand is mediated by four functional units: rapidly adapting type 1 (RA1), slowly adapting type 1 (SA1), rapidly adapting type 2 (RA2), and slowly adapting type 2 (SA2). Each unit consists of an afferent fiber, the fiber's distal branches, and the receptor organ(s) that surround the axon terminals (Table 23–1).

Type 1 fibers terminate in clusters of small receptors in the superficial layers of the skin at the margin between the dermis and epidermis (Figure 23–1). RA1 fibers are the most numerous tactile afferents in the hand, reaching a density of approximately 2 per mm² at the fingertip in man and monkey. The RA1 receptor organ, the Meissner corpuscle, is a globular, fluid-filled structure that encloses a set of flattened, lamellar cells

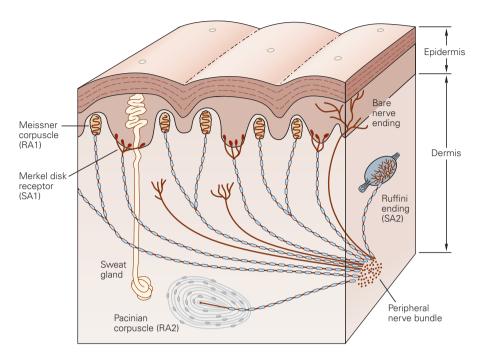

Figure 23–1 Four mechanoreceptors are responsible for the sense of touch. A cross section of the glabrous skin shows the principal receptors for touch. All of these receptors are innervated by large-diameter myelinated fibers. The Meissner corpuscles and Merkel cells lie in the superficial layers of the skin at the base of the epidermis, 0.5 to 1.0 mm below the skin surface. The Meissner corpuscles border the edges of each papillary ridge, whereas the Merkel cells form dense bands surrounding the

sweat gland ducts along the center of the ridges. The RA1 and SA1 fibers that innervate these receptors branch at their terminals so that each fiber innervates several nearby receptor organs. The Pacinian and Ruffini corpuscles lie within the dermis (2–3 mm thick) and deeper tissues. The RA2 and SA2 fibers that innervate these receptors each innervate only one receptor organ. (RA1, rapidly adapting type 1; RA2, rapidly adapting type 2; SA1, slowly adapting type 1; SA2, slowly adapting type 2.)

Table 23-1 Cutaneous Mechanoreceptor Systems

	Type 1		Type 2	
	SA1	RA1 ¹	SA2	RA2 ²
Receptor	Merkel cell	Meissner corpuscle	Ruffini ending	Pacinian corpuscle
Location	Tip of epidermal sweat ridges	Dermal papillae (close to skin surface)	Dermis	Dermis (deep tissue)
Axon diameter (µm)	7–11	6–12	6–12	6–12
Conduction velocity (ms)	40-65	35–70	35–70	35–70
Best stimulus	Edges, points	Lateral motion	Skin stretch	Vibration
Response to sustained indentation	Sustained with slow adaptation	None	Sustained with slow adaptation	None
Frequency range (Hz)	0-100	1–300		5–1,000
Best frequency (Hz)	5	50		200
Threshold for rapid indentation or vibration (best) (μ m)	8	2	40	0.01

¹Also called RA, QA, or FA1.

RA1, rapidly adapting type 1; RA2, rapidly adapting type 2; SA1, slowly adapting type 1; SA2, slowly adapting type 2.

²Also called PC or FA2.

originating from the myelin sheath (see Figure 21–6). The lamellae are coupled mechanically to the edge of the papillary ridge by collagen fibers, a relationship that confers fine mechanical sensitivity to frictional forces as the hand is moved across surfaces (Box 23–1). An RA1 axon typically innervates 10 to 20 Meissner corpuscles, integrating information from several adjacent papillary ridges. Each Meissner corpuscle is innervated by 2 to 5 RA1 axons (Figure 23–3A).

SA1 fibers are also widely distributed in the skin, particularly in the fingertips. The SA1 receptor

organs, the Merkel cells, consist of small epithelial cells that surround the terminal branches of an axon. Each Merkel cell encloses a semirigid structure that transmits compressive strain to the sensory nerve ending. Because there are synapse-like junctions between the Merkel cells and the SA1 axon terminals, it has been proposed that the mechanosensitive ion channels reside in the Merkel cells rather than in the nerve endings. Merkel cells are densely clustered in the center of each papillary ridge in glabrous skin (Figure 23–3A), placing them in an excellent position

Box 23–1 Fingerprint Structure Enhances Touch Sensitivity in the Hand

The histological structure of glabrous skin—the smooth, hairless skin of the palm and fingertips—plays a crucial role in the hand's sensitivity to touch. The fingerprints are formed by a regular array of parallel ridges in the epidermis, the papillary ridges (Figure 23–2).

Each ridge is bordered by epidermal folds—the limiting ridges—that are visible as thin lines on the fingers and palm border. The limiting ridges increase the stiffness and rigidity of the skin, protecting it from damage when contacting objects or when walking barefooted.

The fingerprints give the glabrous skin a corrugated, rough structure that increases friction, allowing us to grasp objects without slippage. Frictional forces

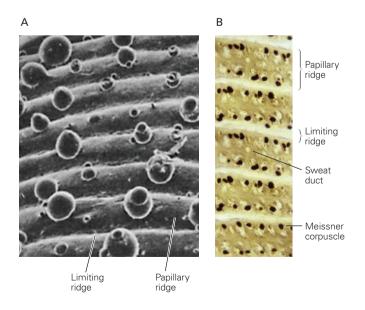

are augmented further when these ridges contact the textured surfaces of objects. Smooth surfaces slide easily underneath the fingers and thus require greater grip force to maintain stability in the hand; the screw caps on bottles are often ridged to make them easy to turn. Frictional forces between the limiting ridges and objects also amplify surface features when we palpate them, allowing us to detect small irregularities such as the grain of wood.

The regular spacing of the papillary ridges—and the precise localization of specific receptors within this grid—allow us to repeatedly scan surfaces with back and forth hand movements while preserving a constant spatial alignment of adjacent surface features.

Figure 23-2 The skin of the finger.

A. Scanning electron micrograph of the fingerprints in the human index finger. The glabrous skin of the hand is structured as arrays of papillary ridges and intervening sulci (limiting ridges) that recur at regular intervals. Globules of sweat exude from ducts at the center of the papillary ridges, forming a grid-like pattern along each ridge. The Merkel cells are located in dense clusters along the center of the papillary ridges between the ducts (see Figure 23–1). (Adapted, with permission, from Quilliam 1978.)

B. Histological section of the glabrous skin cut parallel to the skin surface. The cholinesterase-stained Meissner corpuscles form regularly spaced chains along both sides of each papillary ridge. Thus Meissner corpuscles and Merkel cells form alternating bands of RA1 and slowly adapting type 1 (SA1) touch receptors that span each fingerprint ridge. (Adapted, with permission, from Bolanowski and Pawson 2003.)

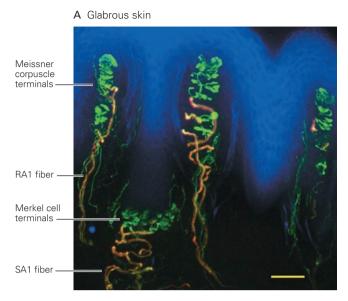

Figure 23–3 Innervation pattern of Meissner corpuscles and Merkel cells in hairy and glabrous skin.

A. A confocal transverse section of a papillary ridge in the human glabrous skin shows the innervation of mechanore-ceptors in the fingertip. Meissner corpuscles are located just below the epidermis (blue) at the apex of the ridge, and are innervated by two or more rapidly adapting type 1 (RA1) fibers. The fibers lose their myelin sheaths (orange) when entering the receptor capsule, exposing broad terminal bulbs at which sensory transduction occurs (green). Individual slowly adapting type 1 (SA1) fibers innervate groups of Merkel cells clustered

Merkel

B Hairv skin

at the base of the intermediate ridge, providing localized signals of pressure applied to that ridge. Scale bar = $50 \mu m$. (Adapted, with permission, from Nolano et al. 2003.)

SA1 fiber

B. A higher-magnification micrograph portrays antibody-labeled Merkel cells (**red**) innervated by an SA1 fiber (**green**). Each fiber extends multiple branches parallel to the surface of the skin that allow it to integrate tactile information from multiple receptor cells in a small zone of skin. The diameter of each Merkel cell is approximately 10 μ m. (Adapted, with permission, from Snider 1998.)

to detect deformation of the overlying skin, either from pressure above or lateral stretch. In hairy skin Merkel cells are localized in small clusters called touch domes (Figure 23–3B).

Type 2 fibers innervate the skin sparsely and terminate in single large receptors in the deeper layers of the dermis or in the subcutaneous tissue (Figure 23–1). The receptors are larger and less numerous than the receptor organs of the type 1 fibers. The large size of these receptors allows them to sense mechanical displacement at some distance from the sensory nerve endings.

The RA2 fibers terminate in Pacinian corpuscles located in the subcutaneous tissue (Figure 23–1). Each RA2 axon terminates without branching in a single Pacinian corpuscle, and each Pacinian corpuscle receives but a single RA2 axon. Pacinian corpuscles are large onion-like structures in which successive layers of connective tissue are separated by fluid-filled spaces. These layers surround the unmyelinated RA2 ending and its myelinated axon up to one or more nodes of Ranvier. The capsule amplifies high-frequency vibration, a role that is important for tool use. Estimates of

the number of Pacinian corpuscles in the human hand range from 2,400 in the young to 300 in the elderly.

The SA2 fibers innervate Ruffini endings concentrated at the finger and wrist joints and along the skin folds in the palm; they are relatively rare in the fingertips. The Ruffini endings are elongated fusiform structures that enclose collagen fibrils extending from the subcutaneous tissue to folds in the skin at the joints, in the palm, or in the fingernails. The SA2 nerve endings are intertwined between the collagen fibers in the capsule, and are excited by stimuli that stretch the receptor along its long axis.

Receptive Fields Define the Zone of Tactile Sensitivity

Individual mechanoreceptor fibers convey information from a limited area of skin called the receptive field. Tactile receptive fields have been determined in the human hand using microneurography.

Åke Vallbo and Roland Johansson inserted microelectrodes through the skin into the median or ulnar nerves in the human hand and recorded the responses of individual afferent fibers. They found that in humans, as in other primate species, there are important differences between touch receptors, both in their physiological responses and in the structure of their receptive fields.

Type 1 fibers have small, highly localized receptive fields with multiple spots of high sensitivity that reflect the branching patterns of their axons in the skin (Figure 23–4). Receptive fields on the fingertips are the

smallest on the body, averaging 11 mm² for SA1 fibers and approximately 25 mm² for RA1 fibers. The fields are small because of the high density of receptors in the fingertips. Receptive fields become progressively larger on the proximal phalanges and the palm, consistent with the lower density of mechanoreceptors in these regions.

In contrast, type 2 fibers innervating the deep layers of skin are connected to only a single Pacinian corpuscle or Ruffini ending. Because these receptors are

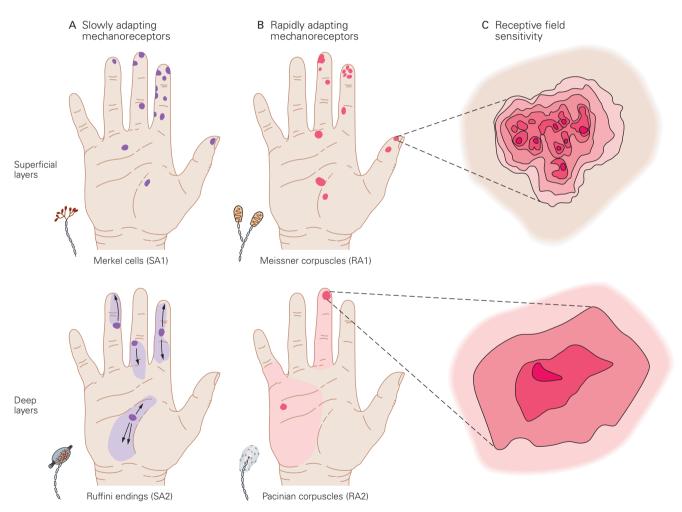

Figure 23–4 Receptive fields in the human hand are smallest at the fingertips. Each colored area on the hands indicates the receptive field of an individual sensory nerve fiber. (Adapted, with permission, from Johansson and Vallbo 1983.)

A–B. The receptive fields of receptors in the superficial layers

A–B. The receptive fields of receptors in the superficial layers of skin encompass spot-like patches of skin. Those of receptors in the deep layers extend across wide regions of skin (light shading), but responses are strongest in the skin directly over the receptor (dark spots). The arrows indicate the directions of skin stretch that activate SA2 fibers.

C. Pressure sensitivity throughout the receptive field is shown as a contour map. The most sensitive regions are indicated in red and the least sensitive areas in pale pink. The receptive field of an RA1 fiber (above) has many points of high sensitivity, marking the positions of the group of Meissner corpuscles innervated by the fiber. The receptive field of an RA2 fiber (below) has a single point of maximum sensitivity overlying the Pacinian corpuscle. The receptive field of SA1 fibers is similar to that of RA1 fibers. Likewise, the receptive field of SA2 fibers resembles that of RA2 fibers.

large they collect information from a broader area of skin. Their receptive fields contain a single "hot spot" where sensitivity to touch is greatest; this point is located directly above the receptor (Figure 23–4).

The receptive fields of type 1 fibers are significantly smaller than most objects that contact the hand. Thus RA1 and SA1 fibers detect small pieces of an object, signaling the properties of only a portion of its surface. As in the visual system, the spatial features of objects are distributed across a population of stimulated receptors with responses that are integrated in the brain to form a unified percept.

Two-Point Discrimination Tests Measure Texture Perception

The ability of humans to resolve spatial details of textured surfaces depends on which part of the body is contacted. Tactile acuity is highest on the fingertips and the lips, where receptive fields are smallest (Figure 23–5A). The separation that defines performance midway between chance and perfect discrimination, the threshold for spatial acuity, is approximately 1 mm on the fingertips of young adults; by the sixth or seventh decade of life it declines on average to approximately 2 mm. When we grasp an object we can discriminate features of its surface separated by as little as 0.5 mm. Humans are able to distinguish horizontal from vertical orientation of gratings with remarkably narrow spacing of the ridges (Figure 23–5B).

Tactile acuity is slightly greater in women than in men and varies between fingers but not between hands. The distal pad of the index finger has the keenest sensitivity; spatial acuity declines progressively from the index to the little finger and declines rapidly at locations proximal to the distal finger pads. Tactile spatial resolution is 50% poorer at the distal pad of the little finger and six to eight times coarser on the palm.

Tactile acuity on proximal parts of the body decreases in parallel with the growing size of receptive fields of SA1 and RA1 fibers (Figure 23–5A). When a pair of probes is spaced several millimeters apart on the hand, each of them is perceived as a distinct point because they produce separate dimples in the skin and stimulate nonoverlapping populations of SA1 and RA1 receptors. As the probes are moved closer together, the two sensations become blurred because both probes are contained within the same receptive field. The spatial interactions between tactile stimuli form the basis of neurological tests of two-point discrimination and texture recognition.

Blind individuals use the fine spatial sensitivity of SA1 and RA1 fibers to read Braille. The Braille

alphabet represents letters as simple dot patterns that are easy to distinguish by touch (Figure 23–6). A blind person reads Braille by moving the fingers over the dot patterns. This hand movement enhances the sensations produced by the dots.

Because the Braille dots are spaced approximately 3 mm apart, a distance greater than the receptive field diameter of an SA1 fiber, each dot stimulates a different set of SA1 fibers. An SA1 fiber fires a burst of action potentials as a dot enters its receptive field and is silent once the dot leaves the field (Figure 23–6). Specific combinations of SA1 fibers that fire synchronously signal the spatial arrangement of the Braille dots. RA1 fibers also discriminate the dot patterns, enhancing the signals provided by SA1 fibers.

Slowly Adapting Fibers Detect Object Pressure and Form

The most important functional feature of the slowly adapting fibers (SA1 and SA2) is their ability to signal skin deformation and pressure. The sensitivity of an SA1 receptor to edges, corners, points, and curvature provides information about object shape, size, surface texture, and compliance. We perceive an object as hard or rigid if it indents the skin, and soft if the skin surface instead deforms the object.

Paradoxically, as an object's diameter increases, the responses of individual SA1 fibers become weaker and the sensation less distinct. For example, the tip of a pencil pressed 1 mm into the skin feels sharp, unpleasant, and highly localized at the contact point, whereas a 1 mm indentation by the eraser feels blunt and broad. The weakest sensation is evoked by a flat surface pressed against the finger pad (Figure 23–7).

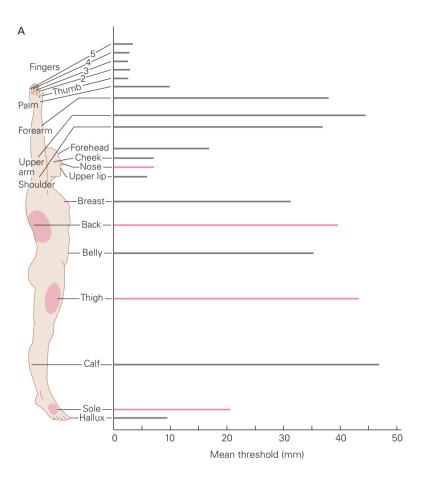

To understand why these objects evoke different sensations, we need to consider the physical events that occur when the skin is touched. When a pencil tip is pressed against the skin it dimples the surface at the contact point and forms a shallow, sloped basin in the surrounding region (approximately 4 mm in radius). Although the indentation force is concentrated in the center, the surrounding region is also perturbed by local stretch, called tensile strain. SA1 receptors at both the center and the surrounding "hillsides" of skin are stimulated, firing spike trains proportional to the degree of local stretch.

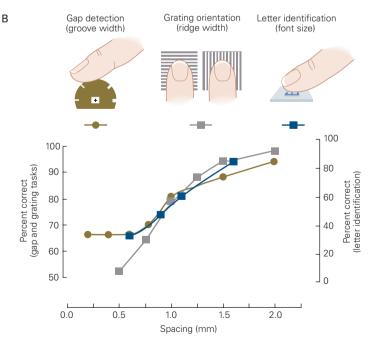

If a second probe is pressed close to the first one, more SA1 fibers are stimulated but the neural response of each fiber is reduced because the force needed to displace the skin is shared between the two probes. Ken Johnson and his colleagues have shown that as more probes are added within the receptive field, the

A. The two-point threshold measures the minimum distance at which two stimuli are resolved as distinct. This distance varies for different body regions; it is approximately 2 mm on the fingers, but as much as 10 mm on the palm and 40 mm on the arm, thigh, and back. The two-point perceptual thresholds highlighted in pink match the diameters of the receptive fields of receptors in the pink zones on the body. The greatest discriminative capacity is afforded in the fingertips, lips, and tongue, which have the smallest receptive fields. (Adapted, with permission, from Weinstein 1968.)

B. Spatial acuity is measured in psychophysical experiments by having a blindfolded subject touch a variety of textured surfaces. As shown here, the subject is asked to determine whether the surface of a wheel is smooth or contains a gap, whether the ridges of a grating are oriented across the finger or parallel to its long axis, or which letters appear on raised type used in letterpress printing. The tactile acuity threshold is defined as the groove width, ridge width, or font size that yields 75% correct performance (detectable midway between chance and perfect accuracy). The threshold spacing on the human fingertip is 1.0 mm in each of these tests. (Adapted, with permission, from Johnson and Phillips 1981.)

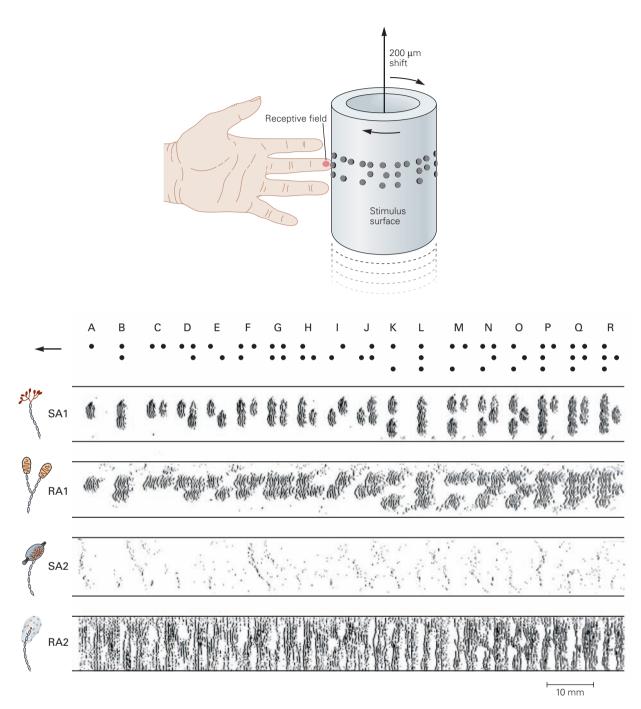

Figure 23–6 Responses of touch receptors to Braille dots scanned by the fingers. The Braille symbols for the letters A through R were mounted on a drum that was repeatedly rotated against the fingertip of a human subject. Following each revolution the drum was shifted upward so that another portion of the symbols was scanned across the finger. Microelectrodes placed in the median nerve of this subject recorded the responses of the mechanoreceptive fibers innervating the fingertip. The action potentials discharged by the nerve fibers as the Braille symbols were moved over the receptive field are represented in these records by small dots; each horizontal row of dots represents the responses of the fiber to a single revolution of the drum. The SA1 receptors register the sharpest

image of the Braille symbols, representing each Braille dot with a series of action potentials and falling silent when the spaces between Braille symbols provide no stimulation. RA1 receptors provide a blurred image of the Braille symbols because their receptive fields are larger, but the individual dot patterns are still recognizable. Neither RA2 nor SA2 receptors are able to encode the Braille patterns because their receptive fields are larger than the dot spacing. The high firing rate of the RA2 fibers reflects the keen sensitivity of Pacinian corpuscles to vibration. (RA1, rapidly adapting type 1; RA2, rapidly adapting type 2; SA1, slowly adapting type 1; SA2, slowly adapting type 2.) (Reproduced, with permission, from Phillips, Johansson, and Johnson 1992.)

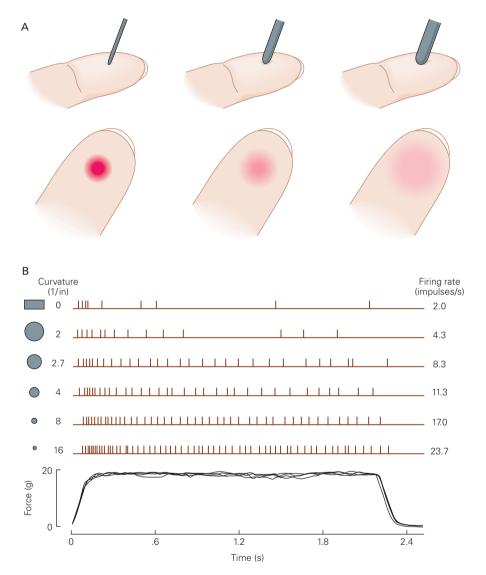

Figure 23–7 Slowly adapting type 1 (SA1) fibers encode the shape and size of objects touching the hand.

A. The area of contact on the skin determines the firing rate and total number of SA1 fibers stimulated. The pink region on the fingertip shows the spread of excitation when probes of different diameters are pressed upon the skin with constant force. The intensity of color is proportional to the firing rates of the stimulated receptors. A small-diameter, sharply pointed probe (left) activates a small population of SA1 receptors. The activated fibers fire intensely because all of the force is concentrated in a small area. A medium-size probe (middle) excites more receptors, but the spread of the force reduces peak firing rates. The probe does not feel as sharp as the small-diameter probe. A large round probe (right) stimulates a large population

of SA1 receptors spread across the width of the finger. These fibers fire at low rates because the force is spread over a wide area of skin. The sensation of pressure is diffuse. (Adapted, with permission, from Goodwin, Browning, and Wheat 1995.)

B. The firing rate of an individual SA1 fiber is determined by the probe diameter. When a probe first contacts the skin, the SA1 response is strong regardless of probe diameter. During steady pressure the firing rate is proportional to the curvature of each probe. The highest firing rates are evoked by the smallest probe, while the weakest responses are produced by flat surfaces and gently rounded (large diameter) probes. The tip's curvature is expressed as the inverse of its spherical radius. (Adapted, with permission, from Srinivasan and LaMotte 1991.)

response intensity of each fiber becomes progressively weaker because the displacement forces on the skin are distributed across the entire contact zone. Thus the skin mechanics results in a case of "less is more." Individual SA1 fibers respond more vigorously to a small object than to a large one because the force needed to indent the skin is concentrated at a small contact point. In this manner each SA1 fiber integrates the local skin indentation profile within its receptive field.

The sensitivity of SA1 receptors to local stretch of the skin also enables them to detect edges, the places where an object's curvature changes abruptly. SA1 firing rates are many times greater when a finger touches an edge than when it touches a flat surface.

The indentation force of a flat or gently curved surface is distributed symmetrically within the central contact zone, whereas the force applied by an object boundary displaces the skin asymmetrically, beyond the edge as well as at the edge. This asymmetric distribution of force produces enhanced responses from receptive fields located along the edges of an object. As edges are often perceived as sharp, we tend to grasp objects on flat or gently curved surfaces rather than by their edges.

The SA2 fibers that innervate Ruffini endings respond more vigorously to stretch of the skin than to indentation because the receptors are located along the palmar folds or at the finger joints. The SA2 fibers therefore provide information about the shape of large objects grasped with the entire hand, the "power grasp" in which all five fingers press an object against the palm. They also provide information about hand shape and finger movements when the hand is empty. If the fingers are fully extended and abducted we feel the stretch in the palm and proximal phalanges as the glabrous skin is flattened. Similarly, if the fingers are fully flexed, forming a fist, we feel the stretch of the skin on the back of the hand, particularly over the metacarpal-phalangeal and proximal interphalangeal joints.

The SA2 system may play a central role in stereognosis—the recognition of three-dimensional objects using touch only—as well as other perceptual tasks in which skin stretch is a major cue. Benoni Edin has shown that SA2 innervation in the hairy skin plays a substantial role in the perception of hand shape and finger position. The SA2 fibers aid the perception of finger joint angle by detecting skin stretch around the knuckles. The Ruffini endings near these joints are aligned such that different groups of receptors are stimulated as the fingers move in specific directions (Figure 23–4A). In this manner the SA2 system provides a neural representation of skin stretch over the entire hand, a proprioceptive rather than exteroceptive function.

Rapidly Adapting Fibers Detect Motion and Vibration

The RA1 receptor organ, the Meissner corpuscle, detects events that produce low-frequency, low-amplitude skin motion. This includes hand motion over the surface of objects, the detection of microscopic surface features, and low-frequency vibration. RA1 fibers contribute to detection of Braille patterns because they sense the change in skin indentation as individual dots pass over their receptive fields (Figure 23–6). They can detect irregularities and bumps as small as $10~\mu m$. We use the sensitivity of RA1 fibers to motion to adjust grip force when we grasp an object.

The RA2 receptor, the Pacinian corpuscle, is the most sensitive mechanoreceptor in the somatosensory system. It is exquisitely responsive to high-frequency (30–500 Hz) vibratory stimuli, and can detect vibration of 250 Hz in the nanometer range (Figure 23–8). The buzzing sensation experienced when a tuning fork is pressed against the skin in a neurological examination is mediated by the synchronized firing of RA2 units. It is a useful measurement of dynamic sensitivity to touch, particularly in cases of localized nerve damage.

The Pacinian corpuscle's filtering and amplifying of high-frequency vibration allows us to feel conditions at the working surface of a tool in our hand as if our fingers themselves were touching the object under the tool. The clinician uses this exquisite sensitivity to guide a needle into blood vessel and to probe tissue stiffness. The auto mechanic can use vibratory sense to position wrenches on unseen bolts. We can write in the dark because we feel the vibration of the pen as it contacts the paper and transmits the resulting frictional forces from the surface roughness to our fingers.

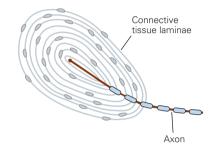

Both Slowly and Rapidly Adapting Fibers Are Important for Grip Control

In addition to their role sensing the size, shape, and texture of objects, mechanoreceptors provide important information concerning the actions of the hand during skilled movements. Roland Johansson and Gören Westling used microneurography to determine the role of mechanoreceptors when objects are grasped in the hand. By placing microelectrodes in the median nerve, they were able to record the firing patterns of individual mechanosensitive fibers as an object was initially contacted by the fingers, grasped between the thumb and index finger, lifted, held above a table, lowered, and returned to the rest position.

They found that all four classes respond to grasp and that each fiber type monitors a particular function.

A Neural coding of vibration

1 Pacinian corpuscle

B Thresholds for detection of vibration

1 Human perceptual thresholds

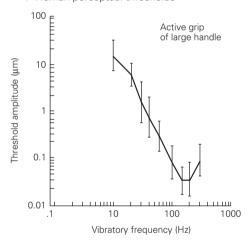

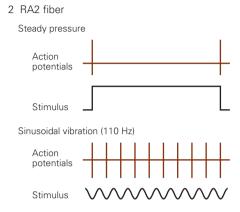

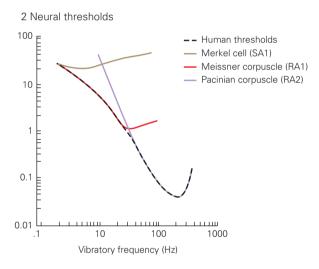

Figure 23–8 Rapidly adapting type 2 (RA2) fibers encode vibration. Vibration is the sensation produced by sinusoidal stimulation of the skin, as by the hum of an electric motor, the strings of a musical instrument, or the tuning fork used in the neurological examination.

A. 1. The Pacinian corpuscle consists of concentric, fluid-filled lamellae of connective tissue that encapsulate the terminal of an RA2 fiber. This structure is uniquely suited to the detection of motion. Sensory transduction in the RA2 fiber occurs in stretch-sensitive cation channels linked to the inner lamellae of the capsule. 2. When steady pressure is applied to the skin the RA2 fiber fires a burst at the start and end of stimulation. In response to sinusoidal stimulation (vibration) the fiber fires at regular intervals such that each action potential signals one cycle of the stimulus. Our perception of vibration as a rhythmically repeating event results from the simultaneous activation of many RA2 units, which fire in synchrony.

B. 1. Psychophysical thresholds for detection of vibration depend on the stimulation frequency. As shown here, humans can detect vibrations as small as 10 nm at 200 Hz when grasping a large object; the threshold is higher at other frequencies and when tested with small probes. (Adapted, with permission, from Brisben, Hsiao, and Johnson 1999.) 2. The neural threshold for detection of vibration is defined as the lowest stimulus intensity that evokes one action potential per cycle of the sinusoidal stimulus. Each type of mechanosensory fiber is most sensitive to a specific range of frequencies. Slowly adapting type 1 (SA1) fibers are most sensitive between 0.3 Hz and 3 Hz, rapidly adapting type 1 (RA1) fibers between 2 Hz and 50 Hz, and RA2 fibers between 30 Hz and 500 Hz. Human thresholds for vibration match those of the most sensitive touch fibers in each range. (Adapted, with permission, from Mountcastle, Lynch, and Carli 1972; Bolanowski et al. 1988.)

The RA1, RA2, and SA1 fibers detect contact when an object is first touched (Figure 23–9). The SA1 fibers signal the amount of grip force applied by each finger, and the RA1 fibers sense how quickly the grasp is applied. The RA2 fibers detect the small shock waves transmitted through the object when it is lifted from the table and placed on another surface. We know when an object makes contact with the table top because of these vibrations and therefore can manipulate the object without looking at it. The RA1 and RA2 fibers cease responding after grasp is established. The SA2 fibers signal flexion or extension of the fingers during grasp or release of the object and thereby monitor the hand posture as these movements proceed.

Signals from the hand that report on the shape, size, and texture of an object are important factors governing the application of force during grasping. Johansson and his colleagues have shown that we lift and manipulate an object with delicacy—with grip forces that just exceed the forces that result in overt slip—and that the grip force is adjusted automatically to compensate for differences in the friction coefficient between surfaces. Subjects predict how much force is required to grasp and lift an object and modify the grip force based on the tactile information provided by SA1 and RA1 afferents. Objects with smooth surfaces are grasped more firmly than those with rough textures, properties coded by RA1 afferents during initial contact of the hand with an object. The significance of the tactile information in grasping is seen in cases of nerve injury or during local anesthesia of the hand; patients apply unusually high grip forces, and the coordination between the grip and load forces applied by the fingers is poor.

The information supplied by the RA1 receptors to monitor grasping actions is critical for grip control, allowing us to hold on to objects when perturbations cause them to slip unexpectedly. RA1 fibers are silent during steady grasp and usually remain quiet until the object is returned to rest and the grasp released. However, if the object is unexpectedly heavy or jolted by external forces and begins to slip from the hand, the RA1 fibers fire in response to the small tangential movements of the object. The net result of this RA1 activity is that grip force is increased by signals from the motor cortex.

Tactile Information Is Processed in the Central Touch System

As described in Chapter 22, the central touch system comprises the dorsal column tracts of the spinal cord, relay nuclei in the brain stem and thalamus, and a hierarchy of

regions in the cerebral cortex (see Figure 22–11). Tactile information enters the cerebral cortex through the primary somatosensory cortex (S-I) in the postcentral gyrus of the parietal lobe.

The neurons in S-I are at least three synapses beyond the receptors in the skin. Their inputs represent information processed in the dorsal column nuclei, the thalamus, and the cortex itself. Each cortical neuron receives inputs arising from receptors in a specific area of the skin, and these inputs together are its receptive field. We perceive that a particular location on the skin is touched because a specific population of neurons in the brain is activated. This experience can be experimentally induced by electrical stimulation of the same cortical neurons.

The primary somatic sensory cortex comprises four cytoarchitectural areas: Brodmann's areas 3a, 3b, 1, and 2 (Figure 23–10A). These areas are extensively interconnected such that processing of sensory information at this level involves both serial and parallel processing. Neurons in areas 3a and 3b receive inputs from the lateral and medial zones of the ventral posterior nucleus of the thalamus and project their axons to areas 1 and 2 (Figure 23–10B). Areas 3b and 1 receive information from receptors in the skin, whereas areas 3a and 2 receive proprioceptive information from receptors in muscles, joints, and the skin.

Somatosensory information is conveyed in parallel from the four areas of S-I to higher centers in the cortex, including the secondary somatosensory cortex (S-II), the posterior parietal cortex, and the primary motor cortex.

Cortical Receptive Fields Integrate Information from Neighboring Receptors

The receptive fields of cortical neurons are much larger than those of mechanoreceptive fibers in peripheral nerves. For example, the receptive fields of SA1 and RA1 fibers innervating the fingertip are tiny spots on the skin, whereas those of the cortical neurons receiving these inputs cover an entire fingertip or several adjacent fingers (Figure 23–11). The receptive field of a neuron in area 3b represents a composite of inputs from 300 to 400 sensory nerve fibers.

Receptive fields in higher cortical areas are even larger, spanning functional regions of skin that are activated simultaneously during motor activity. These include the tips of several adjacent fingers, or both the fingers and the palm. Receptive fields of neurons in the posterior parietal cortex and S-II are often bilateral, including symmetric positions on the contralateral and ipsilateral hands.

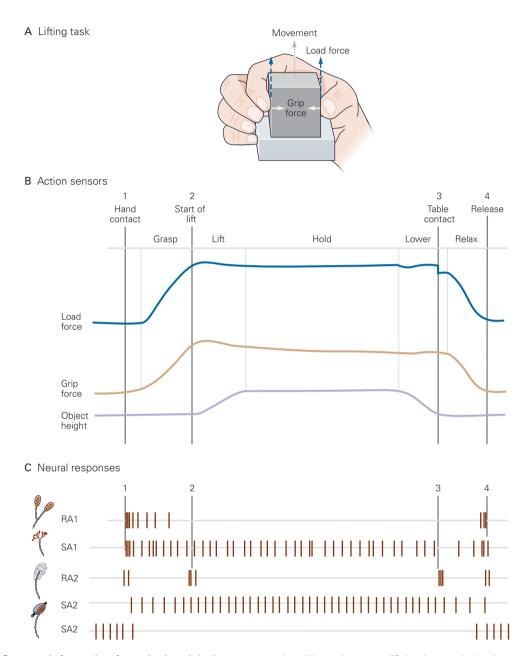

Figure 23–9 Sensory information from the hand during grasping and lifting. (Adapted, with permission, from Johansson 1996.)

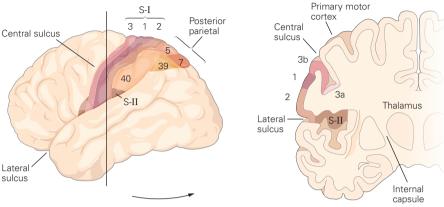

A. The subject grasps and lifts a block between the thumb and fingertips, holds it above a table, and then returns it to the resting position. The normal (grip) force secures the object in the hand, and the tangential (load) force overcomes gravity. The grip force is adapted to the surface texture and weight of the object.

B. The grip and load forces are monitored with sensors in the object. These forces are coordinated following contact with

the object, plateau as lift begins, and relax in concert after the object is returned to the table.

C. All four mechanoreceptors detect hand contact with the object but each monitors a different aspect of the action as the task progresses. SA1 fibers encode the grip force and SA2 fibers the hand posture. RA1 fibers encode the rate of force application and movement of the hand on the object. RA2 fibers sense vibrations in the object with each movement: at hand contact, lift-off, table contact, and release of grasp. (RA1, rapidly adapting type 1; RA2, rapidly adapting type 2; SA1, slowly adapting type 1; SA2, slowly adapting type 2.)

A Somatosensory cortex

B Afferent flow of tactile information

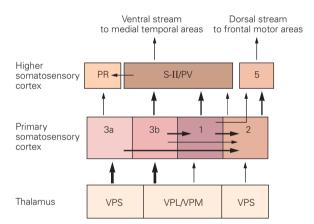

Figure 23–10 The somatosensory areas of the cerebral cortex

A. The somatosensory areas of cortex lie in the parietal lobe and consist of three major divisions. The primary somatosensory cortex (S-I) forms the anterior part of the parietal lobe. It extends throughout the postcentral gyrus beginning at the bottom of the central sulcus, extending posteriorly to the postcentral sulcus, and into the medial wall of the hemisphere to the cingulate gyrus (not shown). The S-I comprises four distinct cytoarchitectonic regions: Brodmann's areas 3a, 3b, 1, and 2. The secondary somatosensory cortex (S-II) is located on the upper bank of the lateral sulcus (Sylvian fissure) and on the parietal operculum; it covers Brodmann's area 43. The posterior parietal cortex surrounds the intraparietal sulcus on the lateral surface of the hemisphere, extending from the postcentral sulcus to the parietal-occipital sulcus and medially to the precuneus. The superior parietal lobule (areas 5 and 7) is a somatosensory area; the inferior parietal lobule (areas 39

and 40) receives both somatosensory and visual inputs. A coronal section through the postcentral gyrus illustrates the anatomical relationship of S-I, S-II, and the primary motor cortex (area 4). S-II lies lateral to area 2 in S-I and extends medially along the upper bank of the lateral sulcus to the insular cortex. The primary motor cortex lies rostral to area 3a within the wall of the central sulcus.

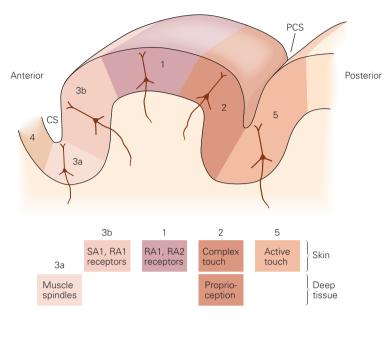

B. Hierarchical connections to and from S-I. Neurons projecting from the thalamus send their axons mainly to areas 3a and 3b, but some thalamic neurons also project to areas 1 and 2. In turn, neurons in cortical areas 3a and 3b project to areas 1 and 2. Information from the four areas of S-I is conveyed to neurons in the posterior parietal cortex (area 5) and S-II. (PR, parietal rostroventral cortex; PV, parietal ventral cortex; VPL, ventral posterior lateral nuclei; VPM, ventral posterior medial nuclei; VPS, ventral posterior superior nuclei.) (Adapted, with permission, from Felleman and Van Essen 1991.)

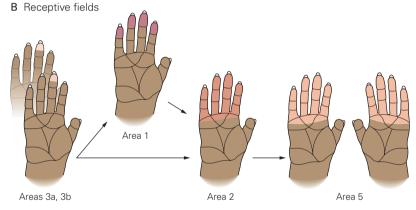

Figure 23–11 The receptive fields of neurons in the primary somatic sensory cortex.

A. This sagittal section illustrates the rostrocaudal anatomy of the four regions of S-I (areas 3a, 3b, 1, and 2) as well as the primary motor cortex (area 4) and the posterior parietal cortex (area 5). The four regions process different types of somatosensory information. Neurons in area 3a receive inputs from muscle spindles and other deep receptors. Neurons in area 3b receive inputs from specific classes of touch receptors in the skin. Neurons in areas 1 and 2 receive convergent inputs from multiple types of somatosensory receptors innervating the same body part. Neurons in area 5 are active mainly during active hand movements.

B. Typical receptive fields of neurons in each area of S-I in monkeys are shown in colors corresponding to those in A. (Receptive fields were measured by applying light touch to the skin.) The receptive fields are smallest in area 3b, where tactile information first enters the cortex. They are progressively larger in areas 1, 2, and 5, reflecting convergent inputs from neurons in area 3b that are stimulated together when we use the hand. Many neurons in area 5 and in S-II cortex have bilateral receptive fields because they respond to touch at mirror image locations on both the contralateral and ipsilateral hands. These neurons enable bilateral coordination when the two hands work synergistically. (CS, central sulcus; PCS, postcentral sulcus; RA1, rapidly adapting type 1; RA2, rapidly adapting type 2; SA1, slowly adapting type 1; SA2, slowly adapting type 2.) (Adapted, with permission, from Gardner 1988; Iwamura et al. 1993; Iwamura, Iriki, and Tanaka 1994.)

A Inputs to areas of primary somatic sensory cortex

The size and position of receptive fields on the skin are not fixed permanently but can be modified by experience or by injury to sensory nerves (see Chapter 17). Cortical receptive fields appear to be formed during development and maintained by simultaneous activation of the input pathways.

The receptive fields of cortical neurons usually have an excitatory zone surrounded by or superimposed upon inhibitory zones (Figure 23–12). Stimulation of regions of skin outside the excitatory zone may reduce the neuron's responses to tactile stimulation within the receptive field. Similarly, repeated stimulation within the receptive field may also decrease neuronal responsiveness because the excitability of the pathway is diminished by inhibition.

Inhibitory receptive fields created by feed-forward and feedback connections through interneurons in the dorsal column nuclei, the thalamus, and the cortex itself limit the spread of excitation. Inhibition generated by strong activity in one circuit reduces the output of nearby neurons that are only weakly excited. The inhibitory networks ensure that the strongest of several competing responses is transmitted, permitting a winner-take-all strategy. These circuits prevent blurring of tactile details such as texture when large populations of touch neurons are stimulated. In addition, higher centers in the brain use inhibitory circuits to focus attention on relevant information from the hand when it is used in skilled tasks, by suppressing unwanted, distracting inputs during such behaviors.

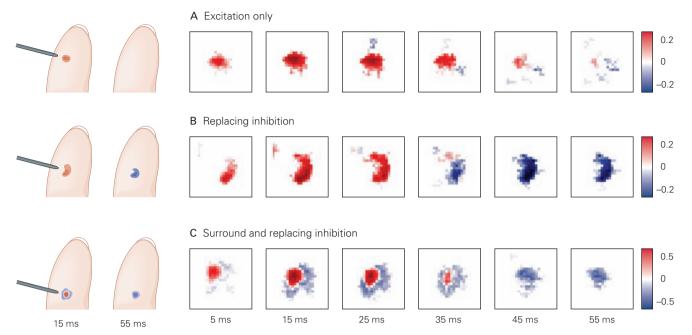

Figure 23–12 Excitatory and inhibitory zones of receptive fields of neurons in area 3b. The excitability of cortical neurons varies over time and as a function of the stimulus location on the skin. Peak excitation occurs in the middle of the receptive field 15 to 25 ms following brief taps on the skin. Inhibition occurs shortly thereafter and is strongest at 45 ms. Delayed inhibition allows each stimulus to be perceived as a distinct event when delivered at rates lower than 25 Hz. Each map indicates the intensity of excitation (red) and inhibition (blue) produced over 10 ms periods following brief taps to a small patch of skin on the fingertip. Cortical neurons vary in the

relative strength and spatial location of excitatory and inhibitory fields. (Adapted, with permission, from Sripati et al. 2006.)

A. Purely excitatory responses occur in only 6% of area 3b neurons.

B. In 42% of neurons in area 3b initial excitation is replaced by inhibition in response to subsequent tactile stimulation of the same skin region.

C. The majority of neurons in area 3b (52%) are excited by stimulation in an excitatory zone and inhibited by stimulation in the surrounding inhibitory zone.

Neurons in the Somatosensory Cortex Are Organized into Functionally Specialized Columns

In a series of pioneering studies of the cerebral cortex, Vernon Mountcastle discovered that the cortex is organized into vertical columns or slabs. Each column is 300 to 600 µm wide and spans all six cortical layers from the surface to the white matter. All of the neurons within a column receive inputs from the same local area of the receptor sheet and respond to the same class or classes of receptors (Figure 23–13). A column is therefore an anatomical structure that, by organizing inputs that convey related information on location and modality, comprises an elementary functional module of the cortex.

Although the receptive fields of the neurons comprising a column in the somatosensory cortex are not precisely congruent, they share a common center that is most clearly evident in layer IV. In addition, the neurons in a column usually process only one submodality, such as pressure or vibration. This is not surprising, as the somatosensory submodalities are conveyed in anatomically separate pathways, and within these pathways the different types of mechanoreceptive fibers are also segregated (see Chapter 22).

The columnar organization of the cortex is a direct consequence of the intrinsic cortical circuitry and the migration pathway of neuroblasts during cortical development. The pattern of connections within the cerebral cortex is oriented vertically, perpendicular to the cortical surface. Thalamocortical axons terminate mainly on clusters of stellate cells neurons in layer IV, the axons of which project vertically toward the surface of the cortex (Figure 23–13B). The apical dendrites and axons of cortical pyramidal cells are also oriented vertically, parallel to the stellate cell axons. Thus the thalamocortical input is relayed to a narrow column of pyramidal cells with apical dendrites that are contacted by the stellate cell axons. This means that the same information is relayed up

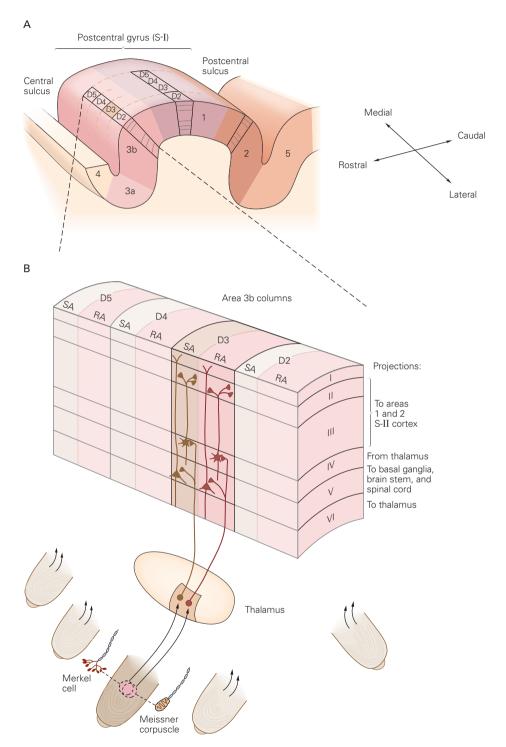

Figure 23–13 Columnar organization of the somatosensory cortex.

A. In each region of the somatic sensory cortex, inputs from the skin or deep tissue are organized in columns of neurons that run from the surface of the brain to the white matter. Each column receives input from one part of the body, here the individual fingers D2 to D5.

B. Details of the columnar organization of tactile inputs from the fingers in a portion of area 3b. Adjacent columns represent adjacent fingers, and for each finger alternating columns of neurons receive inputs from rapidly adapting (RA) and slowly adapting (SA) receptors. Neurons in each cortical layer send their output to specific regions of the brain. (Adapted, with permission, from Kaas et al. 1981; Sur, Wall, and Kaas 1984.)

and down through the thickness of the cortex in a columnar fashion.

The sensory properties computed in each column are output in parallel to multiple regions of the brain. Neurons in each of the six cortical layers project to specific targets. Horizontal connections within layers II and III link neurons in neighboring columns, allowing them to share information when activated simultaneously by the same stimulus. For this reason, neurons in these supragranular layers have larger receptive fields than neurons in layer IV. Neurons in layers II and III also project to other cortical regions, both on the same side of the brain and at mirror locations in the other hemisphere. These feed-forward connections to higher cortical areas allow complex signal integration, as detailed later in this chapter.

Neurons in layer V receive inputs from layers II and III in the same and adjacent columns; they project to subcortical structures, including the basal ganglia, the pontine and other brain stem nuclei, the spinal cord, and the dorsal column nuclei. Layer VI neurons project to the thalamus.

In addition to feed-forward signals of information from mechanoreceptors, recurrent signals from layers II and III of higher brain areas are provided to layer I in each column. These feedback signals originate not only in somatosensory areas of the brain, but also in sensorimotor areas of the posterior parietal cortex, frontal motor areas, limbic areas, and regions of the medial temporal lobe involved in memory formation and storage. The recurrent signals are thought to play a role in the selection of sensory information for cognitive processing (by the mechanisms of attention) and in short-term memory tasks. Feedback pathways may also be involved in the gating of sensory signals during motor activity.

Figure 23–14 (Opposite) Each region of the primary somatosensory cortex contains a neural map of the entire body surface. (Adapted, with permission, from Nelson et al. 1980; Pons et al. 1985.)

A. The primary somatosensory cortex in the macaque monkey lies caudal to the central sulcus as in the human brain. The colored areas correspond to the homologous Brodmann's areas of the human brain shown in Figure 23–10A. Area 5 in the macaque monkey is homologous to areas 5 and 7 in humans. Area 7 in the macaque monkey is homologous to areas 40 and 39 in humans.

B. Body maps in the postcentral gyrus of the primary somatosensory cortex of the macaque monkey obtained from microelectrode recordings. In the diagram the cortex is unfolded along the central sulcus (**dotted line** that parallels the border between

Cortical Columns Are Organized Somatotopically

The columns within the primary somatic sensory cortex are arranged such that there is a complete somatotopic representation of the body in each of the four areas (3a, 3b, 1, and 2). The cortical map of the body corresponds roughly to the spinal dermatomes (see Figure 22–9). Sacral segments are represented medially, lumbar and thoracic segments centrally, cervical segments more laterally, and the trigeminal representation of the head at the most lateral portion of S-I cortex (Figure 23–14). Knowledge of the neural map of the body in the brain is important for localizing damage to the cortex from stroke or head trauma.

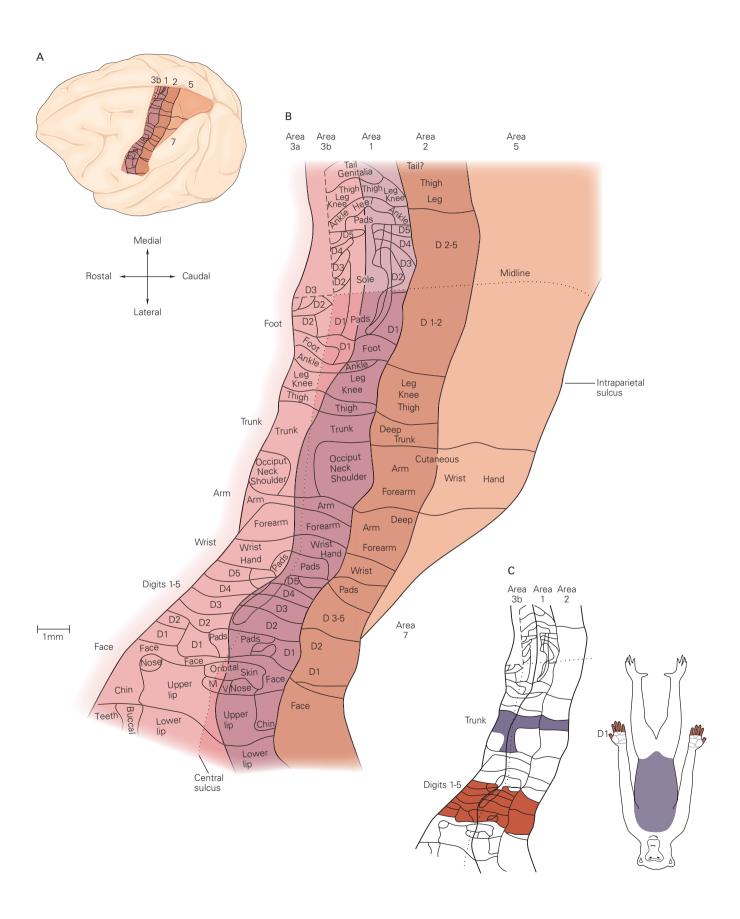

Another important feature of somatotopic maps is the amount of cerebral cortex devoted to each body part. A neural map of the body in the brain does not duplicate exactly the spatial topography of the skin. Rather, it has disproportionately large areas devoted to certain body regions, particularly the hand, foot, and mouth, and relatively smaller areas devoted to more proximal body parts (see Figure 16–6). Each part of the body is represented in proportion to its importance to the sense of touch. Thus more cortex is devoted to the fingers than to the entire trunk (Figure 23–14C).

The amount of cortical area devoted to a unit area of skin—called the *cortical magnification*—varies by more than a hundredfold across different body surfaces. It is closely correlated with the innervation density and thus the spatial acuity of the mechanoreceptors in an area of skin. The areas with greatest magnification—the lips, tongue, fingers, and toes—have tactile spatial thresholds of 0.5, 0.6, 1.0, and 4.5 mm, respectively.

Brain regions activated by tactile stimuli have been visualized with high-resolution optical imaging

areas 3b and 1). The upper part of the diagram includes cortex unfolded from the medial wall of the hemisphere. The body surface is mapped to columns within rostrocaudal bands arranged in the order of the spinal dermatomes. The maps in areas 3b and 1 form mirror images of the distal-proximal or dorsal-ventral axes of each dermatome. Each finger (D5–D1) has its own representation in areas 3b and 1, along the medial-lateral axis of the cortex, but inputs from several adjacent fingers converge in the receptive fields of neurons in area 2.

C. The finger-representation areas occupy a larger expanse of cortex than the trunk-representation areas. Although the trunk (violet) is covered by a greater area of skin than the fingers (red), the number of cortical columns responding to touch on the fingers is nearly three times the number activated by touching the trunk.

of intrinsic signals generated by capillary blood flow. Cortical responses to air puffs applied to each finger of a monkey's hand are strongest in narrow transverse bands across areas 3b and 1 (Figure 23–15). Although inputs from neighboring fingers are organized in sequential bands, there is significant overlap between them, especially for the areas activated by digits 3 through 5, which are generally used in concert. The thumb and index finger, which often operate independently, have distinct territories and occupy a slightly larger cortical area, reflecting their importance in hand function.

Jon Kaas and his collaborators noted that somatotopic maps are important neurologically because they allow functionally related neurons to interconnect efficiently. For example, horizontal connections between cortical columns representing adjacent fingers enable us to perceive the surfaces contacted by different fingers as a continuous surface. The proximity of neurons representing the hand and mouth is likely to be useful in feeding behaviors, particularly in humans and other primates that bring food to the mouth with their hands.

The body surface has at least 10 distinct neural maps in the parietal lobe: four in S-I, four in S-II, and at least two in the posterior parietal cortex. Microelectrode mapping studies in monkeys have shown that the four areas of S-I (3a, 3b, 1, and 2) each have a complete, separate somatotopic representation of the body surface specific to a particular somatic sensory modality (Figure 23–14B). Area 3a receives input primarily from muscle stretch receptors; area 3b receives input from both SA1 and RA1 fibers; area 1 receives input primarily from RA1 and RA2 fibers; and area 2 contains a map of both touch and proprioception (Figure 23–11A).

As a result, these regions mediate different aspects of somatic sensation. Areas 3b and 1 are involved in sensing the details of surface texture, whereas area 2 is responsible for sensing the size and shape of objects. These attributes of somatic sensation are further elaborated in S-II and the posterior parietal cortex, where they form the basis of cognitive acts (object discrimination) and motor acts (object manipulation).

Touch Information Becomes Increasingly Abstract in Successive Central Synapses

As we have seen, the responses of mechanoreceptors to Braille dot patterns or embossed letters touched by the fingers faithfully encode the stimulus contours (see Figure 23–6) and specify precisely where on the hand touch occurs. The sharp sensory images encoded by

receptors in the skin are preserved up to the first stage of cortical processing in area 3b.

As information flows toward higher-order cortical areas, specific combinations of stimuli or stimulus patterns are needed to excite individual neurons. Neurons in areas 1 and 2 of S-I are concerned with more abstract features than just the location of a tactile stimulus. Neurons with receptive fields that include more than one finger fire at higher rates when several fingers are touched, and thus are concerned with the size of objects held in the hand.

Signals from neighboring neurons are combined in higher cortical areas to discern global properties of objects such as their orientation on the hand, the direction of motion across the skin (Figure 23–16), and their shape. In general, cortical neurons are concerned with sensory features that are independent of the stimulus position in their receptive field, allowing the brain to represent patterns common to stimuli of a particular class.

A cortical neuron is able to detect the orientation of an edge or the direction of motion because of the spatial arrangement of the presynaptic receptive fields. The receptive fields of the excitatory presynaptic neurons are aligned along a preferred axis; a stimulus orientation that matches the alignment elicits a strong excitatory response. In addition, the receptive fields of inhibitory presynaptic neurons at one side of the excitatory fields reinforce the orientation and direction selectivity of the postsynaptic cell (Figure 23–17).

Convergent inputs from different sensory modalities allow neurons in higher cortical areas to detect the size and shape of objects. Whereas neurons in area 3b and 1 respond only to touch, and neurons in area 3a respond to muscle stretch, many of the neurons in area 2 receive both inputs. Thus neurons in area 2 can integrate information on the hand posture used to grasp an object, the grip force applied by the hand, and the tactile stimulation produced by the object, and this integrated information allows us to recognize the object.

Cognitive Touch Is Mediated by Neurons in the Secondary Somatosensory Cortex

An S-I neuron's response to touch depends almost exclusively on input within the neuron's receptive field. This feed-forward pathway is often described as a *bottom-up* process because the receptors in the periphery are the principal source of excitation of S-I neurons.

Higher-order somatosensory areas receive information not only from peripheral receptors, but also are strongly influenced by top-down processes, such as goal setting and attentional modulation. Data obtained from single-neuron studies in monkeys, neuroimaging

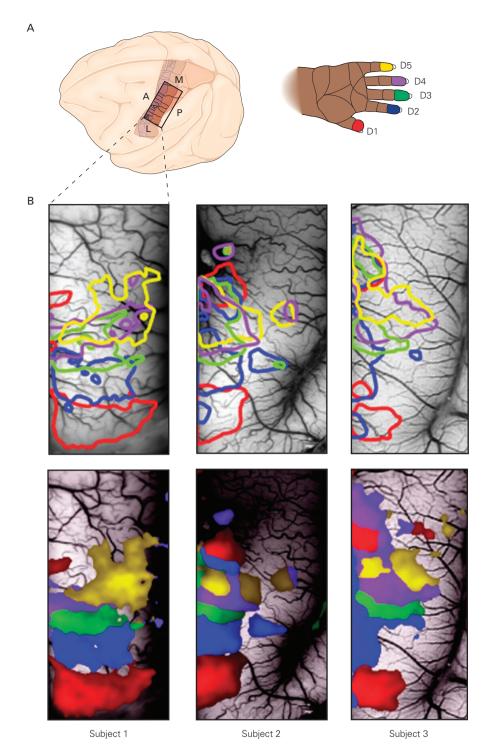

Figure 23–15 The representation of single fingers in S-I cortex follows a common plan. High-resolution optical imaging of intrinsic signals visualizes the areas of sensory cortex that represent each digit and allows one to identify precisely the neural representation of the hand. (Reproduced, with permission, from Shoham and Grinvald 2001.)

A. A schematic dorsal view of the macaque brain outlines the cortical territory explored with brain imaging.

B. The somatotopic organization of the hand area in three monkeys is superimposed on brain images of S-I cortex. The anterior part of each brain image shows Brodmann's area 1, and the posterior part shows areas 2 and 5. Although each animal has a distinctive map of the hand, all three have the same topographical organization.

Top: Outlines of the cortical regions activated by air puffs applied to individual digits are superimposed on the surface vasculature image. The outline colors correspond to the colors shown on each digit in part A. The regions stimulated by each digit are similar in total area. The regions responding to digits 3 to 5 overlap, whereas those activated by the thumb (red) and index finger (blue) do not.

Bottom: The information from the maps for each digit is integrated using a winner-take-all rule. The colors designate the digit that gave the strongest response; the intensity encodes the amplitude of the response to the "winning" digit. The domains of digits 3 to 5 appear as narrow stripes in the winner-take-all maps because of the larger overlap between their activated cortical areas.

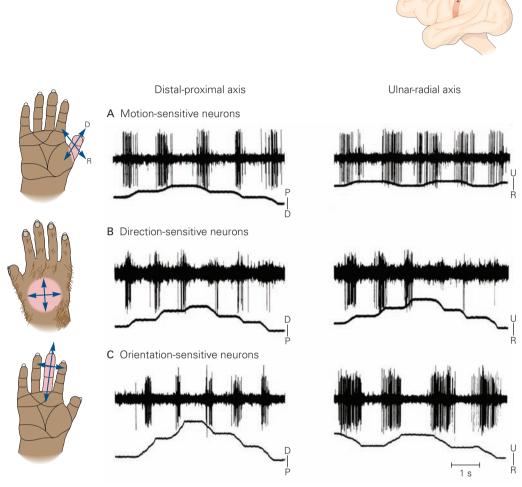

Figure 23–16 Neurons in area 2 encode complex tactile information. These neurons respond to motion of a probe across the receptive field but not to touch at a single point. The lower trace indicates the direction of motion by upward and downward deflections. (Adapted, with permission, from Warren, Hämäläinen, and Gardner 1986.)

A. A motion-sensitive neuron responds to stroking the skin in all directions.

B. A direction-sensitive neuron responds strongly to motion toward the ulnar side of the palm but fails to respond to motion in the opposite direction. Responses to distal or proximal movements are weaker.

C. An orientation-sensitive neuron responds better to motion across a finger (ulnar-radial) than to motion along the finger (distal-proximal), but does not distinguish ulnar from radial nor proximal from distal directions.

studies in humans, and clinical observations of patients with lesions in higher-order somatosensory areas suggest that the ventral and dorsal regions of the parietal lobe serve complementary functions in the touch system similar to the dorsal (what) and ventral (where) pathways of the visual system (see Chapter 25).

Like S-I, the S-II cortex contains four distinct anatomical subregions with separate maps of the body. In both humans and monkeys S-II is located on the upper

bank and adjacent parietal operculum of the Sylvian or lateral fissure (see Figure 23–10A). The central zone—consisting of S-II proper and the adjacent parietal ventral area—receives its major input from areas 3b and 1, largely tactile information from the hand and face. A more rostral region, the parietal rostroventral area, receives information from area 3a about active hand movements (Figure 23–18). The most caudal somatosensory region of the lateral sulcus extends onto the

parietal operculum. This region abuts the posterior parietal cortex and plays a role in integrating somatosensory and visual properties of objects.

Physiological studies indicate that S-II plays a key role in the use of touch to recognize objects placed in the hand. S-II neurons are essential for distinguishing spatial features such as shape and texture and temporal properties such as vibratory frequency. Although neurons in S-II respond to textures such as Braille dots, embossed letters, or gratings, their pattern of firing does not encode the spatial or temporal patterns of the stimuli. Instead, they simply fire at different rates for different patterns. Similarly, they do not represent vibration as periodic spike trains linked to the oscillatory frequency, as do the sensory fibers from the skin. Instead, their firing rates also depend on behavioral context or motivational state.

In an elegant study Ranulfo Romo and his colleagues compared responses of neurons in S-I, S-II, and various regions of the frontal lobe of monkeys while the animals performed a two-alternative forced-choice task (Figure 23–19). The animals were rewarded if they correctly recognized which of two vibratory stimuli was higher in frequency. Neurons in S-I faithfully represented

the vibratory cycles each stimulus, firing a brief burst in response to each. In contrast, S-II neurons responded to the first stimulus with spike trains proportional to its frequency but responded to the second stimulus with a signal that combined the frequencies of both stimuli. Thus the same vibratory stimulus could evoke different firing rates in S-II, depending on whether the preceding stimulus was higher or lower in frequency.

Romo's group found that neurons in prefrontal and premotor cortex that receive inputs from S-II preserve a memory of the first stimulus, continuing to fire after it ends. They proposed that the memory signal is fed back to S-II from these higher brain regions, modifying the response of S-II neurons to the direct tactile signals from the hand. In this manner sensorimotor memories of previous stimuli influence sensory processing in the brain, allowing us to make cognitive judgments about newly arriving tactile stimuli.

S-II is the gateway to the temporal lobe via the insular cortex. Regions of the medial temporal lobe, particularly the hippocampus, are vital to the storage of explicit memory (see Chapter 67). We do not store in memory every scintilla of tactile information that enters the nervous system, only that which has some behavioral

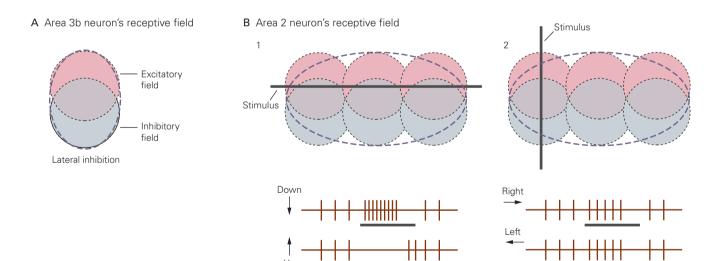

Figure 23–17 The spatial arrangement of excitatory and inhibitory inputs to a cortical neuron determines which features of a stimulus will be encoded by the neuron.

A. A neuron in area 3b of the primary somatosensory cortex has overlapping excitatory and inhibitory zones within its receptive field.

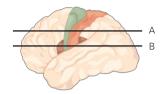

B. Convergence of three presynaptic neurons with the same arrangement of excitatory and inhibitory zones allows direction and orientation selectivity in a neuron in area 2. 1. Downward motion of a horizontal bar across the receptive field of

the postsynaptic cell produces a strong excitatory response because the excitatory fields of all three presynaptic neurons are contacted simultaneously. Upward motion of the bar strongly inhibits firing because it enters all three inhibitory fields first. The neuron responds poorly to upward motion through the excitatory field because the initial inhibition outlasts the stimulus. 2. Motion of a vertical bar across the receptive field evokes a weak response because it simultaneously crosses the excitatory and inhibitory receptive fields of the input neurons. Motion to the left and right are not distinguished in this example.

Figure 23–18 Active touch evokes more complex responses in S-I and S-II than passive touch. Cortical regions in the human brain stimulated by passive and active touch are localized using functional magnetic resonance imaging (fMRI). (Adapted, with permission, from Hinkley et al. 2007.)

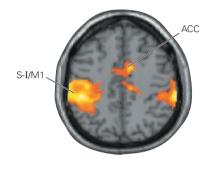

A. Axial views of activity along the central sulcus during passive stroking of the right hand with a sponge (right panel) and during active touching of the sponge (left panel). Areas 3b and 1 are activated in the left hemisphere in both conditions. Active touch also engages the primary motor cortex (M1) in the left hemisphere, the anterior cingulate cortex (ACC), and evokes weak activity in the ipsilateral S-I (right hemisphere). These sites were confirmed independently using magnetoencephalography in the same subjects.

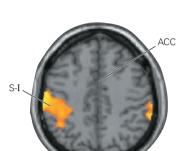

B. Axial views of activity along the Sylvian fissure in the same experiment. Bilateral activity occurs in S-II and the parietal ventral (PV) area during passive stroking and is stronger when the subject actively moves the hand. The parietal rostroventral area (PR) is active only during active touch. Magnetoencephalographic responses in S-II/PV and PR occur later than in S-I, reflecting serial processing of touch from S-I to S-II/PV, and from S-II/PV to PR.

A Activity along the central sulcus (S-I)

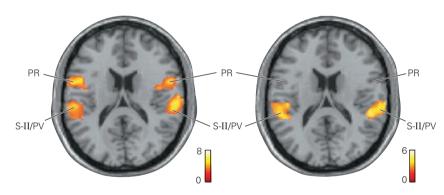

Active touch

Passive touch

B Activity along the lateral sulcus (S-II)

significance. In light of the demonstration that the firing patterns of S-II neurons are modified by selective attention, S-II could make the decision whether a particular bit of tactile information is remembered.

Active Touch Engages Sensorimotor Circuits in the Posterior Parietal Cortex

The posterior parietal regions surrounding the intraparietal sulcus play an important role in the sensory guidance of movement rather than in discriminative touch. In monkeys these regions include areas 5 and 7 and in humans they include the superior parietal (Brodmann's areas 5 and 7) and inferior parietal cortex (areas 39 and 40).

Neurons in medial portions of area 5 receive postural information from SA2 fibers in the skin overlying the wrist, elbow, and shoulder, from receptors deep in these joints, and from muscle spindles that provide information about the movements of the arm. In monkeys these neurons are particularly sensitive when the animal extends its hand to grasp an object. Other cells located more laterally in area 5 integrate tactile and postural information from the hand. They respond most vigorously when the monkey shapes the hand in anticipation of grasping an object or plucks food morsels from a small container.

Neurons in area 7 of the monkey integrate tactile and visual stimuli that overlap in space and thus play an important role in eye-hand coordination. They respond more vigorously when the monkey is able to observe its hand while manipulating objects of interest than when simply looking at the object or handling it in the dark. Firing patterns in area 7 are also correlated with the hand posture used to grasp different objects.

It was originally believed that areas 5 and 7 were higher-order somatosensory areas that processed tactile information for object recognition and shape discrimination, and used proprioceptive signals for internal representations of integrated postures of the limbs. These theories were supported by anatomical data that showed that the principal sensory inputs to area 5 originate in

area 2 of S-I cortex. However, these ideas about the role of areas 5 and 7 had to be altered following the discovery by Vernon Mountcastle, Juhani Hyvärinen, and others that these areas are involved in motor control.

In fact, during reaching and grasping, neural activity in the posterior parietal cortex coincides with activation of neurons in motor and premotor areas of

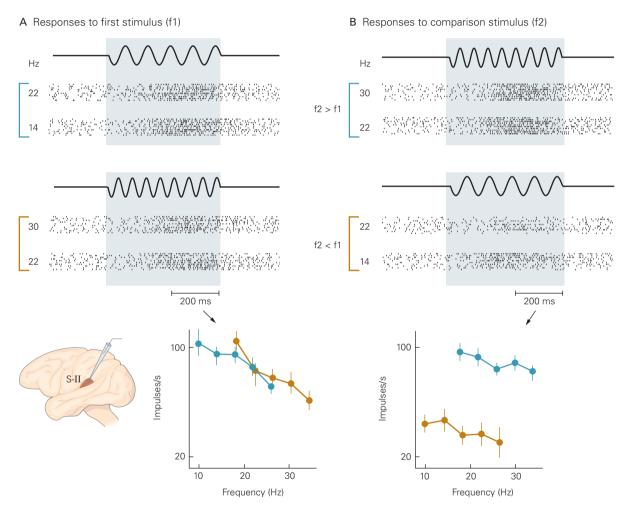

Figure 23–19 The sensitivity of an S-II neuron to vibratory stimuli is modulated by attention and behavioral conditions. A monkey was trained to compare two vibratory stimuli applied to the fingertips (f1 and f2) and to report which had the higher frequency. The plots show the mean firing rates of the neuron during each of the two stimuli. The animal's decision about which frequency is higher can be predicted from the neural data during each type of trial. The mean firing rates of this neuron are significantly higher at each stimulation frequency when f2 is greater than f1 (blue) than when f2 is less than f1 (gold). (Adapted, with permission, from Romo et al. 2002.)

A. Raster plots show the responses of an S-II neuron to various sample stimuli (f1). The vertical tick marks in each row

denote action potentials, and individual rows are separate trials of the stimulus pairs. Trials are grouped according to the frequencies tested. The firing rate of the neuron encodes the vibratory frequency of the sample stimulus; it is higher for low-frequency vibration regardless of the subsequent events.

B. Each row in the raster plots illustrates responses to the comparison stimulus (f2) during the same trials shown in A. The neuron's response to f2 reflects the frequency of both f2 and f1. When f2 > f1 the neuron fires at high rates during f2 and the animal reports that f2 is the higher frequency. When f2 < f1 the neuron fires at low rates during f2 and the animal reports that f1 is the higher frequency. In this manner the responses of S-II neurons reflect the animal's memory of an earlier event.

the frontal cortex and precedes activity in S-I. There is strong evidence that area 5 receives convergent central and peripheral signals that allow it to compare central motor commands with peripheral sensory feedback during reaching and grasping behaviors. Sensory feedback from the hand to the posterior parietal cortex is used to confirm the goal of the planned action, thereby reinforcing a previously learned skill or correcting those plans when errors occur.

Predicting the sensory consequences of hand actions is an important component of active touch. For example, when we view an object and reach for it, we predict how heavy it should be and how it should feel in the hand; we use such predictions to initiate grasping. Daniel Wolpert and Randy Flanagan have proposed that during active touch the motor system controls the afferent flow of somatosensory information so that subjects can predict when tactile information should arrive in S-I and reach consciousness. Convergence of central and peripheral signals allows neurons to compare planned and actual movements. Corollary discharge from motor areas to somatosensory regions of the cortex may play a key role in active touch. It provides posterior parietal neurons with information on intended actions, allowing these neurons to compare planned and actual neural responses to tactile stimuli. Such mechanisms may explain why it is so difficult to tickle oneself.

Lesions in Somatosensory Areas of the Brain Produce Specific Tactile Deficits

Loss of tactile sensation in the hand produces significant motor as well as sensory deficits. Local anesthesia of the hand provides a direct way to appreciate the sensorimotor role of touch.

Loss of touch does not cause paralysis or weakness because much of skilled movement is predictive, relying on sensory feedback for adjustment if necessary. The motor system compensates for the absence of tactile information by generating more force than necessary. Under local anesthesia hand movements are clumsy and poorly coordinated, and force generation during grasping is abnormally slow. With the loss of tactile sensibility one is completely reliant on vision for directing the hand.

These motor problems are further exacerbated by long-term, chronic loss of tactile function because of injury to peripheral nerves or dorsal column lesions. Deafferentation produces major changes in the afferent connections in the brain (see Chapter 18), as do certain diseases. Myelinated afferent fibers in the dorsal columns degenerate in patients with demyelinating

diseases, such as multiple sclerosis. In late-stage syphilis the large-diameter neurons in the dorsal root ganglia are destroyed (tabes dorsalis). These patients have severe chronic deficits in touch and proprioception but often little loss of temperature perception and nociception. The somatosensory losses are accompanied by motor deficits: clumsy and poorly coordinated movements and dystonia.

Similar impairments occur in patients with damage to S-I caused by stroke or head trauma, or following surgical excision of the postcentral gyrus. The severity and extent of the deficit depends on the site of the lesion. The sensory and motor deficits resulting from lesions in various parts of the parietal lobe have been compared in clinical studies.

Patients with lesions in the anterior parietal cortex have severe difficulties with simple tactile tests—touch thresholds, vibration and joint position sense, and two-point discrimination (Figure 23–20A). The patients also perform poorly on more complex tasks, such as texture discrimination, stereognosis, and visual-tactile matching tests. Motor deficits are less pronounced than sensory losses, particularly during tests of force and position control. Exploratory movements and skilled tasks, such as catching a ball or pinching small objects between the fingertips, are also somewhat abnormal.

In contrast, patients with lesions in the posterior parietal cortex have only mild difficulty with simple tactile tests. However, they have profound difficulty with complex tactile recognition tasks, and use few exploratory and skilled movements (Figure 23–20B). They display kinematic deficits when interacting with objects, failing to shape and orient the hand properly to grasp them, and misdirect the arm during reaching. They use too much grip force when an object is placed in their hand and are unable to direct the fingers properly when asked to evaluate its size and shape. These deficits are described clinically as the "useless hand" syndrome (tactile apraxia).

Humans with lesions localized to S-II also cannot perform complex tactile discrimination tasks such as stereognosis, but the deficits appear to be cognitive rather than sensorimotor. Mel Goodale and David Milner found that patients that are unable to discriminate the size of objects in clinical psychophysical tests are able to use visual information to match the shape of the hand to that of an object they must grasp. They propose that the dorsal parietal areas bordering the intraparietal sulcus serve a sensorimotor function, guiding hand movements in handling objects. The ventral somatosensory areas bordering the lateral sulcus serve a cognitive function, allowing us to recognize and name objects and thereby remember them.

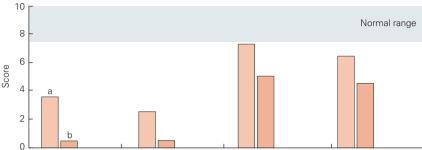

Studies of sensory deficits in human patients are complicated by the fact that disease states or

Figure 23-20 Lesions of anterior and posterior regions of the parietal lobe produce characteristic sensory and motor deficits of the hand. Bar graphs rank the performance of nine patients (a - i) on four sets of standardized tests of sensory and motor function of the hand. The behavioral scores are ranked from normal (10) to maximal deficit (0). The "normal range" shows the performance scores of these patients for the ipsilateral limb. Tests of simple somatosensory function include light touch from a 1 g force-calibrated probe, two-point discrimination on the finger and palm, vibration sense, and position sense of the index finger metacarpophalangeal joint. Tests of complex tactile recognition assess texture discrimination, form recognition, and size discrimination. Tests of hand position and force control measure grip force, tapping, and reaching to a target. Tests of exploratory and skilled movements evaluate insertion of pegs in slots, pincer grip of small objects, and exploratory movements when palpating objects. (Adapted, with permission, from Pause et al. 1989.)

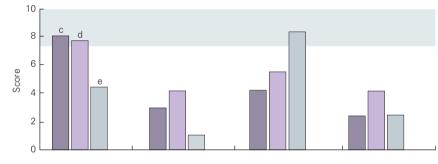

- A. Two patients with lesions to the anterior parietal lobe show severe impairment in both sets of tactile tests but only moderate impairment in the motor tasks.
- B. Three patients with posterior parietal lesions show only minor deficits in simple somatosensory tests but severe impairment in complex tests of stereognosis and form. Motor deficits are greater in skilled tasks.
- C. Four patients with combined lesions to anterior and posterior parietal cortex show severe impairment in all tests. Interestingly, the patient who showed the least impairment in this group (patient f) suffered brain damage at birth; the developing brain was able to compensate for the loss of major somatosensory areas. Lesions in the other patients resulted from strokes later in life.

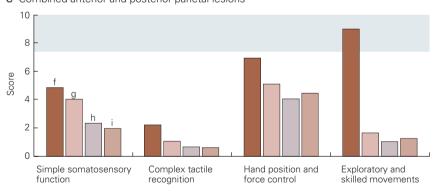

B Posterior parietal lesions

C Combined anterior and posterior parietal lesions

trauma rarely produce a "clean" lesion confined to one localized brain area. For this reason analyses of experimentally controlled lesions in animals have been useful for understanding the etiology of the sensory deficits observed in human patients. For example, macaque monkeys with a lesion of the cuneate fascicle show chronic losses in tactile discrimination, such as higher touch thresholds, impaired vibration sense, and poor two-point discrimination. They also

display major deficits in the control of fine finger movements during grooming, scratching, and manipulation of objects.

A similar deficit in the execution of skilled movements can be produced experimentally in monkeys by inhibiting the neurons in the hand-representation region of area 2. The animal has great difficulty coordinating movements of the fingers because tactile feedback is absent (Figure 23–21).

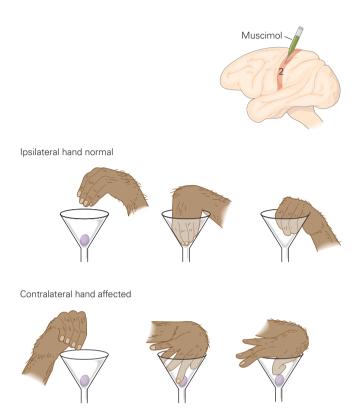

Figure 23–21 Finger coordination is disrupted when synaptic transmission in the somatic sensory cortex is inhibited in a monkey. Muscimol, a γ -aminobutyric acid (GABA) agonist that inhibits cortical cells, was injected into Brodmann's area 2 on the left side of a monkey's brain. Within minutes after injection the finger coordination of the right hand (contralateral) was severely disrupted; the monkey was unable to pick up a grape from a funnel. The injection effects are known to be specific to the injected hemisphere because the left hand (ipsilateral) continues to perform normally. (Adapted, with permission, from Hikosaka et al. 1985.)

Experimental ablation of somatosensory areas of the cortex has provided valuable information about the function of these areas. Small lesions limited to area 3b produce major deficits in touch sensation from a particular part of the body. Lesions in area 1 produce a defect in the assessment of the texture of objects, whereas lesions in area 2 alter the ability to differentiate the size and shape of objects. The resulting damage to tactile function is less severe when such lesions are made in infant animals, apparently because in the developing brain S-II cortex may take over functions normally assumed by S-I.

Removal of S-II cortex in monkeys causes severe impairment in the discrimination of both shape and texture and prevents the animals from learning new tactile discriminations. Ablation of area 5 produces deficits in roughness discrimination but few other alterations in

passive touch. However, motor performance is severely compromised as these animals misdirect reaches to objects and fail to preshape the hand to grasp objects skillfully.

The similarity between the impairments observed in humans and monkeys is an important basis for understanding clinical losses of somatosensory function. We shall learn in later chapters that lesioning studies of other cortical areas in monkeys have also provided insight into higher-order sensory and motor functions of the brain.

An Overall View

When we explore an object with our hands a large part of the brain may become engaged by the sensory experience, by the thoughts and emotions it evokes, and by motor responses to it. These sensations result from the parallel actions of multiple cortical areas engaged in feed-forward and feedback networks.

At the first touch the peripheral sensory apparatus deconstructs the object into tiny segments, distributed over a large population of approximately 20,000 sensory nerve fibers. The SA1 system provides high-fidelity information about its spatial structure that is the basis of form and texture perception. The RA1 system conveys information about motion of the object in the hand, which enables us to manipulate it skillfully. The RA2 receptors transmit information about vibration of objects that allows us to use them as tools. The SA2 system provides information about the hand conformation and posture during grasping and other hand movements.

The information from these mechanoreceptors is conveyed to consciousness by the dorsal column fiber tracts of the spinal cord, relay nuclei in the brain stem and thalamus, and a hierarchy of intracortical pathways. By analyzing patterns of activity across the entire population, the brain constructs a neural representation of the object and the actions of the hand.

Central pathways have four important functions as they process the information from these mechanoreceptors. First, they convey the information provided by the receptors to the cognitive mechanisms responsible for perception. For this function the organization of these pathways is critical. A central theme is specificity: Computations of different kinds are kept separate by parallel pathways and by segregation of function at synaptic relays within single pathways.

Computations in these pathways are complex and accomplished serially, beginning in the dorsal column nuclei, progressing through the thalamus and several cortical stages, and terminating in regions of the medial

temporal cortex concerned with memory and perception and in motor areas of the frontal lobe that mediate voluntary movements.

The brain's processing of touch is aided by the somatotopic organization of the neurons involved at each relay. Adjacent skin areas that are stimulated together are linked anatomically and functionally in central relays. Body parts that are especially sensitive to touch—the hands, feet, and mouth—are represented in large areas of the brain, reflecting the importance of tactile information conveyed from these regions.

The second function of the central pathways is transformation of the disaggregated representation of object properties in thousands of neurons to an integrated representation of complex object properties in a few neurons. Convergent excitatory connections between neurons representing neighboring skin areas and intracortical inhibitory circuits enable higher-order cortical cells to integrate global features of objects. In this manner the somatosensory areas of the brain represent properties common to particular classes of objects.

A third function is regulating the afferent flow of somatosensory information. The peripheral fibers deliver much more information than can be handled at any one moment; the central neural pathways compensate by selecting information for delivery to the mechanisms of perception and memory. Recurrent pathways from higher brain areas modify the ascending information provided by touch receptors, thus fitting the stream of sensory information to previous experience and task goals.

Finally, the touch system provides information necessary for the control and guidance of movement. Interactions between sensory and motor areas of parietal and frontal cortex provide a neural mechanism for predicting the sensory consequences of motor behaviors and for skill learning from repeated experience.

Pain

Noxious Insults Activate Nociceptors

Signals from Nociceptors Are Conveyed to Neurons in the Dorsal Horn of the Spinal Cord

Hyperalgesia Has Both Peripheral and Central Origins

Nociceptive Information Is Transmitted from the Spinal Cord to the Thalamus

Five Major Ascending Pathways Convey Nociceptive Information

Several Thalamic Nuclei Relay Nociceptive Information to the Cerebral Cortex

Pain Is Controlled by Cortical Mechanisms

Cingulate and Insular Areas Are Active During the Perception of Pain

Pain Perception Is Regulated by a Balance of Activity in Nociceptive and Non-Nociceptive Afferent Fibers

Electrical Stimulation of the Brain Produces Analgesia

Opioid Peptides Contribute to Endogenous Pain Control

Endogenous Opioid Peptides and Their Receptors Are Distributed in Pain-Modulatory Systems

Morphine Controls Pain by Activating Opioid Receptors

Tolerance and Addiction to Opioids Are Distinct Phenomena

An Overall View

PAIN DESCRIBES THE UNPLEASANT sensory and emotional experiences associated with actual or potential tissue damage. Pricking, burning, aching, stinging, and soreness are among the most distinctive of all the sensory modalities. As with the other somatic sensory modalities—touch, pressure, and

position sense—pain serves an important protective function, alerting us to injuries that require evasion or treatment. In children born with insensitivity to pain, severe injuries often go unnoticed and can lead to permanent tissue damage. Yet pain is unlike other somatic sensory modalities, or vision, hearing, and smell in that it has an urgent and primitive quality, possessing both affective and emotional components.

The perception of pain is subjective and is influenced by many factors. An identical sensory stimulus can elicit quite distinct responses in the same individual under different conditions. Many wounded soldiers, for example, do not feel pain until they have been removed from the battlefield; injured athletes are often not aware of pain until a game is over. Simply put, there are no purely "painful" stimuli, sensory stimuli that invariably elicit the perception of pain in all individuals. The variability of the perception of pain is yet another example of a principle that we have encountered in earlier chapters: Pain is not the direct expression of a sensory event but rather the product of elaborate processing by the brain of a variety of neural signals.

When pain is experienced it can be acute, persistent, or in extreme cases chronic. Persistent pain characterizes many clinical conditions and is usually the reason that patients seek medical attention. In contrast, chronic pain appears to have no useful purpose; it only makes patients miserable. Pain's highly individual and subjective nature is one of the factors that make it so difficult to define objectively and to treat clinically.

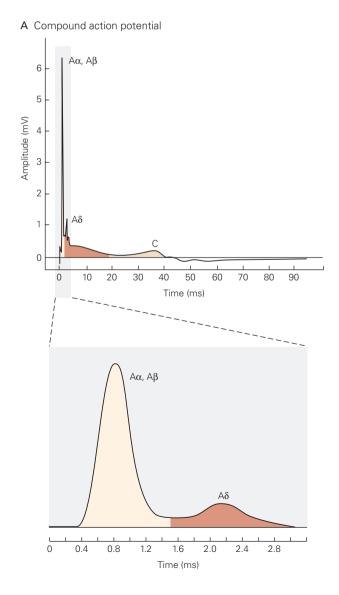

In this chapter we discuss the neural processes that underlie the perception of pain in normal individuals and explain the origins of some of the abnormal pain states that are encountered clinically.

Noxious Insults Activate Nociceptors

Many organs in the periphery, including skin and subcutaneous structures such as joints and muscles, possess specialized sensory receptors that are activated by noxious insults. Unlike the specialized somatosensory receptors for light touch and pressure, most of these *nociceptors* are simply the free nerve endings of primary sensory neurons. There are three main classes of nociceptors—thermal, mechanical, and polymodal—as well as a more enigmatic fourth class, termed silent nociceptors.

Thermal nociceptors are activated by extremes in temperature, typically greater than 45° C (115° F) or less than 5° C (41° F). They are the peripheral endings of small-diameter, thinly myelinated A δ axons that conduct action potentials at speeds of 5 to 30 m/s (Figure 24–1A). *Mechanical nociceptors* are activated optimally by intense pressure applied to the skin; they too are the endings of thinly myelinated A δ axons. *Polymodal nociceptors* can be activated by high-intensity mechanical, chemical, or thermal (both hot and cold) stimuli. This class of nociceptors is found at the ends of small-diameter, unmyelinated C axons that conduct more slowly, at speeds less than 1.0 m/s (Figure 24–1A).

These three classes of nociceptors are widely distributed in skin and deep tissues and are often coactivated.

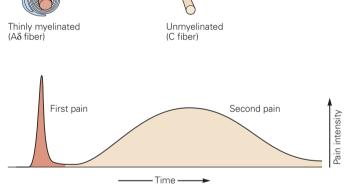

Figure 24–1 Propagation of action potentials in different classes of nociceptive fibers.

A. The speed at which action potentials are conducted is a function of each fiber's cross-sectional diameter. Wave peaks in the figure are labeled alphabetically in order of latency. The first peak and its subdivisions are the summed electrical activity of myelinated A fibers. A delayed (slowly conducting) deflection represents the summed action potentials of unmyelinated C fibers. The compound action potential of the A fibers is shown on a faster time-base to depict the summation of the action potentials of several fibers. (Modified, with permission, from Perl 2007.)

B. First and second pain are carried by two different primary afferent fibers. (Modified, with permission, from Fields 1987.)

When a hammer hits your thumb, you initially feel a sharp pain ("first pain") followed by a more prolonged aching and sometimes burning pain ("second pain") (Figure 24–1B). The fast sharp pain is transmitted by A δ fibers that carry information from damaged thermal and mechanical nociceptors. The slow dull pain is transmitted by C fibers that convey signals from polymodal nociceptors.

Silent nociceptors are found in the viscera. This class of receptors is not normally activated by noxious stimulation; instead, inflammation and various chemical agents dramatically reduce their firing threshold. Their activation is thought to contribute to the emergence of secondary hyperalgesia and central sensitization, two prominent pain syndromes.

Noxious stimuli depolarize the bare nerve endings of afferent axons and generate action potentials that are propagated centrally. How is this achieved? The membrane of the nociceptor contains receptors that convert the thermal, mechanical, or chemical energy of noxious stimuli into a depolarizing electrical potential. One such protein is a member of a large family of so-called transient receptor potential (TRP) ion channels. This receptor-channel, TRPV1, is expressed selectively by nociceptive neurons and mediates the pain-producing actions of capsaicin, the active ingredient of hot peppers, and many other pungent chemicals. The TRPV1 channel is also activated by noxious thermal stimuli, which suggests that it normally transduces the sensation of painful heat. In addition, TRPV1-mediated membrane currents are enhanced by a reduction in pH, a characteristic of the chemical milieu of inflammation.

Additional members of the TRP channel family are expressed by nociceptive neurons, and the variety of TRP channels in nociceptors is thought to underlie the perception of a wide range of temperatures from extreme cold to intense heat. The TRPV2 channel is expressed predominantly in A δ fiber terminals and is activated by very high temperatures, whereas the TRPM8 channel is activated by low temperatures and by chemicals such as menthol (Figure 24–2).

In addition to this constellation of TRP channels, other receptors and ion channels that participate in the transduction of peripheral stimuli are expressed in nociceptive sensory endings. Nociceptors selectively express tetrodotoxin-resistant Na⁺ channels. One Na⁺ channel (SCN9A, also called Na_V1.7) plays a key role in the perception of pain in humans, as revealed by the rare pain-insensitive individuals who possess mutations in the corresponding gene. One class of mutations inactivates the SCN9A channel and results in a complete inability to sense pain. But in all other respects these individuals are healthy and exhibit

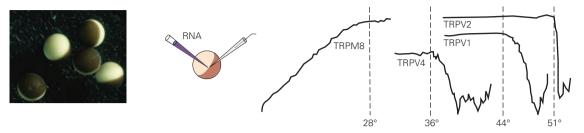

normal sensory responses to touch, mild temperature, proprioception, tickle, and pressure. A second class of mutations in the SCN9A gene changes the inactivation kinetics of this channel; individuals with these mutations exhibit an inherited condition called paroxysmal extreme pain disorder, characterized by rectal, ocular, and submandibular pain.

Nociceptors also express an ionotropic purinergic receptor, PTX3, that is activated by adenosine triphosphate (ATP) released from peripheral cells after tissue damage. In addition, they express members of the Mas-related G protein-coupled receptor (Mrg) family, which are activated by peptide ligands and serve to sensitize nociceptors to other chemicals released in their local environment (see Figure 24–7). These receptors and channels provide attractive targets for the development of drugs with actions selective for nociceptive sensory neurons.

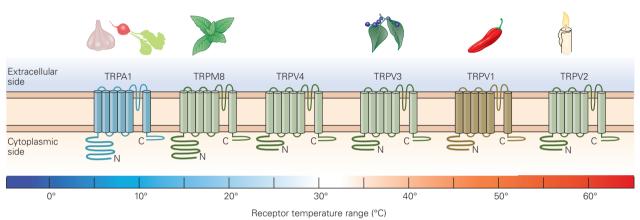

The uncontrolled activation of nociceptors is associated with several pathological conditions. Allodynia and hyperalgesia are two common pain states that reflect changes in nociceptor activity. Patients with *allodynia* feel pain in response to stimuli that are normally innocuous: by a light stroking of sunburned skin, by the movement of joints in patients with rheumatoid arthritis, and even by the act of getting out of bed in the morning after a vigorous workout. Nevertheless, patients with allodynia do not feel pain constantly; in the absence of a peripheral stimulus there is no pain. In contrast, patients with *hyperalgesia*—an exaggerated response to noxious stimuli—typically report persistent pain in the absence of sensory stimulation.

Persistent pain can be subdivided into two broad classes, nociceptive and neuropathic. Nociceptive pain results from the activation of nociceptors in the skin or soft tissue in response to tissue injury, and it usually arises from an accompanying inflammation. Sprains and strains produce mild forms of nociceptive pain, whereas arthritis or a tumor that invades soft tissue produces a much more severe nociceptive pain. Neuropathic pain results from direct injury to nerves in the peripheral or central nervous system and is often accompanied by a burning or electric sensation. Neuropathic pains include the syndromes of reflex sympathetic dystrophy, also called complex regional pain syndrome, and post-herpetic neuralgia, the severe pain experienced by patients after a bout of shingles. Other neuropathic pains include phantom limb pain, the pain that occurs after limb amputation, which we discuss below. In some instances pain can even occur without a peripheral stimulus, a phenomenon termed anesthesia dolorosa. This syndrome can be triggered following attempts to block chronic pain, for example

A Thermosensitivity of TRP channels in Xenopus oocytes

B Thermosensitivity of TRP channels in dorsal root ganglion cells

C Pathway to TRP channel opening

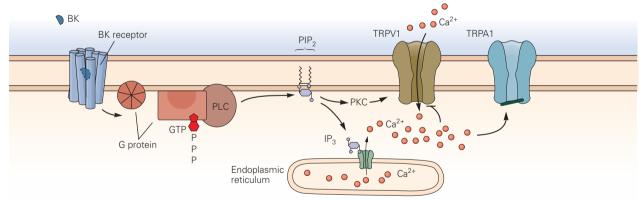

Figure 24–2 Transient receptor potential ion channels in nociceptive neurons.

A. Xenopus oocytes are injected with mRNA encoding transient receptor potential (TRP) channels. Electrophysiological recordings from the oocytes reveal the thermosensitivity of the channels. The temperature (centigrade) at which a specific TRP channel is activated is shown by the downward deflection of the recording. (Photograph on left reproduced, with permission, from Erwin Sigel 1987. Traces on the right reproduced, with permission, from Tominaga and Caterina 2004.)

B. Temperature response profiles of different TRP channels expressed by dorsal root ganglion neurons. (Modified, with

permission, from Jordt, McKemy, and Julius 2003; Dhaka, Viswanath, and Patapoutian 2006.)

C. Bradykinin (BK) binds to G protein-coupled receptors on the surface of primary afferent neurons to activate phospholipase C (PLC), leading to the hydrolysis of membrane phosphatidylinositol bisphosphate (PIP₂), the production of inositol 1,4,5-trisphosphate (IP₃), and the release of Ca²⁺ from intracellular stores. Activation of protein kinase C (PKC) regulates TRP channel activity. The TRPV1 channel is sensitized, leading to channel opening and Ca²⁺ influx. (Modified, with permission, from Bautista et al. 2007.)

after therapeutic transection of sensory afferent fibers in the dorsal roots.

Signals from Nociceptors Are Conveyed to Neurons in the Dorsal Horn of the Spinal Cord

The perception of noxious stimuli arises from signals in the peripheral axonal branches of nociceptive sensory neurons whose cell bodies are located in dorsal root ganglia or the trigeminal ganglia. The central branches of these neurons terminate in the spinal cord in a highly orderly manner. Most terminate in the dorsal horn. Primary afferent neurons that convey distinct sensory modalities terminate in different laminae (Figure 24–3B). Thus there is a tight link between the anatomical organization of dorsal horn neurons, their receptive properties, and their function in sensory processing.

Many neurons in the most superficial lamina of the dorsal horn, termed *lamina I* or the *marginal layer*, respond to noxious stimuli conveyed by $A\delta$ and C fibers. Because they respond selectively to noxious stimulation they have been called *nociception-specific neurons*. This set of neurons projects to higher brain centers, notably the thalamus. A second class of lamina I neurons receives input from C fibers that are activated selectively by intense cold. Other classes of lamina I neurons respond in a graded fashion to both innocuous and noxious mechanical stimulation and thus are termed *wide-dynamic-range neurons*.

Lamina II, the substantia gelatinosa, is a densely packed layer that contains many different classes of local interneurons, some excitatory and others inhibitory. Some of these interneurons respond selectively to nociceptive inputs, whereas others also respond to innocuous stimuli. Laminae III and IV contain a mixture of

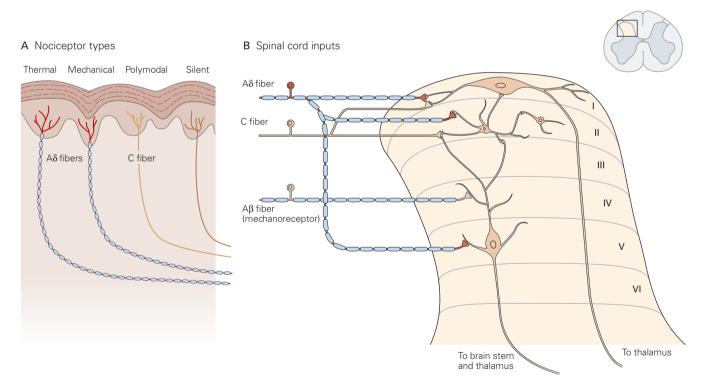

Figure 24–3 Nociceptive fibers terminate in the dorsal horn of the spinal cord.

A. Peripheral nociceptor classes.

B. Neurons in lamina I of the dorsal horn receive direct input from myelinated (A δ) nociceptive fibers and both direct and indirect input from unmyelinated (C) nociceptive fibers via interneurons in lamina II. Lamina V neurons receive low-threshold input from large-diameter myelinated fibers (A β) of

mechanoreceptors as well as inputs from nociceptive afferent fibers (A δ and C fibers). Lamina V neurons send dendrites to lamina IV, where they are contacted by the terminals of A β primary afferents. Dendrites in lamina III arising from cells in lamina V are contacted by the axon terminals of lamina II interneurons. A α fibers innervate motor neurons and interneurons in the ventral spinal cord (not shown). (Modified, with permission, from Fields 1987.)

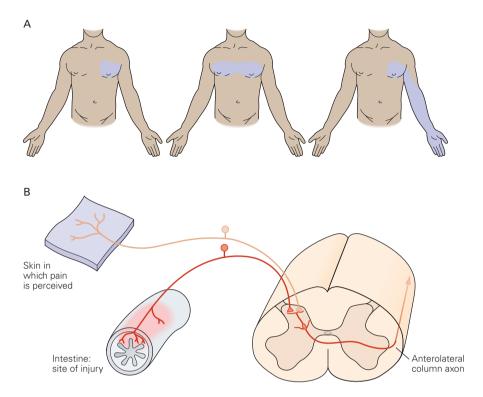

Figure 24–4 Signals from nociceptors in the viscera can be felt as "referred pain" elsewhere in the body.

A. Myocardial infarction and angina can be experienced as deep referred pain in the chest and left arm. The source of the pain can be readily predicted from the site of referred pain.

B. Convergence of visceral and somatic afferent fibers may account for referred pain. Nociceptive afferent fibers from the
